VOL. CXXI, No. 1 NEW YORK, WEDNESDAY, JANUARY 7, 1925 WHOLE No. 2296

Clinical Study of Vascular Spasm*

RUFUS S. REEVES, M.D.
Philadelphia, Pa.

That the condition of vascular spasm is a rare one is well attested by a careful review of the literature: in fact, its rarity is remarked upon by no less a person than Sir Clifford Allbutt. It is mentioned especially in conjunction with intermittent claudication, which is in reality one local example of the condition. As accuracy in diagnosis is the aim of all of us, as upon it depends both treatment and the latters' results, vascular spasm, or angiospasm, must be borne in mind when one is examining cases in which there is present either a hemiplegia, or a monoplegia or aphasia—not to mention edema of an extremity, acute phlebitis, cellulitis or lymphangitis.

With these facts in mind it seemed to me worth while to record a short series of cases which have come under my observation within the past two years.

Angiospasm is seen most frequently in arteriosclerotic patients, though it is not confined entirely to them. Osler is of the opinion that Peabody best explained the condition when discussing the cerebral symptoms of arteriosclerosis by stating that there occurs spasmodic contraction of the muscular coats of the middle cerebral artery or its several branches which in connection with the narrowed lumen (caused by the sclerosis) leads to a decreased blood supply to the brain tissue supplied by the affected artery. The condition may be of short duration and frequently recurs; according to Allbutt, it may terminate in occlusion and thrombosis, generally partial, owing to the lateral projection of the proliferated coat. That Peabody's explanation, noted above, is a correct one, will be brought out in an article soon to appear; a surgeon exposed a vessel in spasm.

It is of interest that André Thomas established in his studies on inducing angiospasm the following symptoms: cramps, numbness, decrease of the local temperature, and disappearance of pulsations. Our findings in some of these cases coincided with his. Exercise does undoubtedly cause spasm—due partly at least to the fact that the amount of blood supplied does not correspond to the demand for the work performed. Intermittent claudication associated with arteriosclerosis frequently appears between the ages of twenty and forty and is of toxic origin, resulting from rheumatism, syphilis or nicotine. The blood pressure readings were subnormal, a fact which is in agreement with the observations of Bernheim.

*From the Medical Service of the Protestant Episcopal Hospital, Philadelphia, Pa.

CASE REPORTS

CASE I.—W. F., aged sixty, admitted to the Episcopal Hospital, April 11, 1922. His chief complaint was numbness, which began the previous day while putting in a gas pipe. He noted a tingling sensation in the left arm and left leg, quit work, walked a few squares and went to bed. Soon there developed a total paralysis of the left leg and partial involvement of the left arm, and the patient was sent in by his family physician. His past history was negative, save for pneumonia at twenty. The patient was a laborer, and denied the use of either alcohol or tobacco.

His father had died at sixty-five with a similar attack, his involvement, however, having been the right arm and right leg and having lasted five weeks. At forty his nephew had a similar attack, lasting three or four months,—the patient was unable to recall the extremities involved. His mother died at sixty-five of "softening of the brain."

Interesting features of his physical examination were: heart, hypertrophied to nipple line, weak muscular tone with accentuated pulmonic second sound, paralysis of left leg and left arm except that there was a slight movement of the fingers. There were no retinal hemorrhages.

BLOOD PRESSURE

	S.	D.	Arm
On admission	130	75	Right
	110	55	Left
April 19, 1922.....	120	55	Right
	145	70	Left
April 21, 1922.....	135	55	Right
	130	45	Left
April 27, 1922.....	140	55	Right
	130	60	Left

During his stay in the hospital he responded promptly to external heat and supportive treatment. Motion slowly returned and he was up and around the ward several days before his discharge. The patient was discharged April 29, 1922.

CASE II.—W. V. C., aged sixty. Admitted to the Episcopal Hospital May 24, 1922. His chief complaint was weakness followed by partial facial

Copyright, 1925, by A. R. Elliott Publishing Company.

paralysis. It began on the morning of the day of admission, while he was working. The first thing he noticed was pain with partial paralysis of the right side of his face, facial movements being very weak. He was sent to the receiving ward immediately with the partial paralysis noted above, and also weakness of the muscles of both arms. He also complained of headache and muttered incoherently. Aside from that his symptoms were negative as were his previous medical history and family history. His social history is that he was an electrical assembling worker; however, he never worked in lead. The salient features of his physical examination were slight hypertrophy of the heart just within the nipple line, the apex beat being in the fifth interspace. The muscular tone was noted as being fair. The ward notes, dated the day following admission, state that there was no noticeable weakness in any groups of muscles. The eyes showed a slight tendency to oscillatory and lateral nystagmus. The left pupil did not close tightly.

On admission his blood pressure was 135 systolic, 75 diastolic, which arm used was not stated. However, on the day after admission it was 130 systolic and 75 diastolic, in both arms. On admission his temperature was 99.3°, pulse 80 and respiration 20. During the six days he was in the hospital his temperature ranged between that on admission and 97°, while the pulse rate was between 60 and 72. All laboratory findings in this case were negative. The patient was discharged June 6, 1922, in extremely good condition.

Case III.—J. McC., aged sixty-four. Admitted to the Episcopal Hospital March 24, 1922. Complained of pain in left chest, pain and weakness in the left arm, and the left foot was swollen from the ankle to the knee. The history of the present illness as noted in the hospital records is entirely barren of any symptoms having a bearing upon the subject of vascular spasm with the exception of the fact that the patient noticed weakness in his left arm. Therefore, the deductions are made from our findings. The social, previous medical and family histories also were negative and valueless as far as our records are concerned.

The physical examination showed the teeth to be in extremely bad condition. The heart was enlarged and muscle tone weak. The eyes showed a slight dilatation of the right pupil. The blood Wassermann was negative. The urine was typically that of an arteriosclerotic, namely, a trace of albumin, low specific gravity, and an occasional hyaline cast. Phthalein elimination was thirty per cent. for the first two hours. Blood urea nitrogen and differential blood count were negative. Red blood cells 3,630,000, white blood cells 21,920. The spinal fluid examination was negative, except that the fluid was under increased pressure. Dr. Kraus, the ophthalmologist, states the disc of the eye was very gray and there was a pulsation of sclerotic vessels. The temperature in the left popliteal space was 97.2°, while that in the right was 95.2°. This difference was noted until May 8th, after which the temperature became even. Before the latter event, there was considerable edema in the left leg. After some improvement from the treatment indicated as a result of his examinations, he was discharged May 19, 1922, our feeling having been that our data and findings were sufficient to warrant his being in the classification of cases mentioned in this paper.

Case IV.—F. B., aged sixty-seven. Admitted April 6, 1922, to the men's medical ward, Episcopal Hospital, with a diagnosis of subdural hemorrhage. The hospital records state that the history of the present illness and in fact all history was unobtainable on admission as the patient was unable to talk, yet understood all commands.

The physical examination showed his teeth to be in extremely poor condition and there was also a pulsation in his neck. The heart was normal in outline and there were no thrills, murmurs or shocks. The abdomen and extremities were negative. The eyes reacted normally to light, but there was a nystagmus to the left and also slight asymmetry to the left. Patellar reflexes were exaggerated. Suggestive Babinski reflex on the left side. The spinal fluid examination was negative, except that the fluid was under moderately increased pressure. The eye examination by Dr. Fewell, the ophthalmologist, was as follows: Pupils dilated—right six mm., left three; color, well defined. Arteries seem reduced in calibre, showing a moderate sclerosis. No discreet lesions in the fundus. O. S. the same. The urine and blood examinations were negative. The blood pressure was 150 systolic, 95 diastolic, in both arms.

The temperature while in the hospital varied between 100° first few days to normal. The pulse was 96 on admission, but soon became normal. The patient was treated with heat and stimulation and his condition improved steadily so that at the time of his discharge, May 27th, he was able to walk around the ward and seemed to have regained the complete use of all the disabled members.

Case V.—M. M. Admitted to the men's medical ward of the Episcopal Hospital June 28, 1923, with a diagnosis of intermittent claudication. Patient stated that while walking down the street three weeks before admission he suddenly felt a sharp pain in the calf of his right leg, so sharp, in fact, that he thought something had struck him. The weakness and pain became more marked and he went home and then to bed. The leg became swollen and extremely warm from the knee joint to the ankle and was sore for about two weeks. The condition improved and he was able to be up and around, but could walk a short distance only, suffering no pain at that time. However, two days before his admission he had another attack of pain similar to the previous one and the leg became swollen again. There were no other cardiovascular symptoms and the remainder of the history, both as far as his family and social histories were concerned, were negative. Previous medical history was also negative as far as acute infections were concerned. He had been a moderate tobacco user, but denied having ever used alcohol.

Physical examination was negative, except that the heart sounds were distinct and of fair quality. The right leg from the knee down showed edema and ecchymosis and pitted on pressure. There was also slight tenderness on deep pressure on the calf of it. The temperature of both the right and left leg was identical and both anterior and posterior tibial arteries pulsated. The blood pressure was not re-

corded. Pulse rate during his stay in the hospital varied between 84 and 76, while his temperature was practically normal. Uranalysis and blood count were negligible. The ward notes state that by July 2d the edema in the right leg had decreased markedly and the yellowish discoloration was disappearing. After application of dry heat his condition improved so markedly that he insisted upon being discharged on the 5th of July, contrary to medical advice.

CASE VI.—J. B., aged fifty-two. Admitted to the men's medical ward of the Episcopal Hospital July 6, 1923. The history was of his having fallen unconscious in a trolley car while on his way to work. Before that time he suffered from headache and mental confusion. While standing on the platform of an elevated car he felt dizzy, had a sharp frontal headache and then became unconscious and remained so until he was brought to the receiving ward of this hospital. He stated that he had had several similar attacks within the last few years.

The patient was a police officer. He drank four cups of coffee a day with an occasional drink of whiskey. Other previous medical and family histories were negative, except when he had these previous attacks he did not void urine, did not froth at the mouth, did not have convulsive movements and did not bite his tongue.

Physical examination showed that the heart was enlarged to the left and the muscular tone was fair. There was a definite sclerosis of the upper vessels of the arm. Laboratory reports were entirely negative. Blood pressure was 124 systolic, 65 diastolic.

This condition improved while resting in bed and we were unable to persuade him to stay in the hospital longer than the eleventh of April.

TREATMENT

The treatment of vascular spasm consists of complete rest in bed, liquid or semisolid diet, continuous application of heat to involved areas and supportive medication.

In arteriosclerotic patients potassium iodide is indicated, while in many cases tincture of belladonna is advised. Morichau Beauchant has advised the use of sodium citrate three to four gm. over long periods.

SUMMARY

1. Vascular spasm is rare.
2. Intermittent claudication is a local example of the condition.
3. It must be borne in mind when any hemiplegia, monoplegia, aphasia, or unilateral edema is seen.

Galvanic and Faradic Electricity and Derived Currents in General Practice*

FRANK THOMAS WOODBURY, M.D.
New York
Lieutenant Colonel, Medical Corps, U. S. Army (Retired).

I shall confine my paper to galvanism, the basis of all electrotherapeutics, faradism and derived currents. We must bear in mind that historically static electricity has been longer connected with medicine than the currents just mentioned. Wickham has said that it is not what is in the machine which interests us as physicians but what comes out of it. I shall, therefore, take this hint. You will, however, permit a few preliminary details of physics as a basis of understanding what follows.

Galvanism is the employment in living tissues of a direct continuous current of electricity. By direct, we mean always flowing in the same direction throughout the application. A current of electricity is conceived of as the flow of electrons from the negative pole of the generator through an external path called the external circuit, back to the positive pole of the generator; the generator resembling a pump and the flow of electrons or current of electricity, a stream of water. For this conception we have mathematical, experimental and practical confirmation.

Benjamin Franklin, before the electrons were known, decided that there were two kinds of electricity, negative and positive, and also that the current flowed from the positive to the negative pole in the external circuit. This need not confuse us, since we always speak of the sun as setting, knowing that in reality it is the western horizon rising. The electrons, therefore, flow from the negative pole or cathode to the positive pole or anode. Cathode means the way down and anode means the way up, also figurative terms.

Comparing electrons to molecules of water and the earth's electrical capacity to sealevel—the generator or sun separates the electrons or molecules of water and by its power raises the water to a high altitude, the electrons to a high state of electrical potential. When the water seeks sea level again, it can give back the energy imparted by the sun, to run mills and hydroelectric plants. In the same way the electrons seeking the earth level or condition of electrical neutrality can give up energy to the various agents in their path, causing heat and incandescence, magnetism, mechanical motion and chemical changes called electrolysis, and when applied to living tissue such physiological changes as sensation of heat and pain, sedation with analgesia, muscular contraction, hyperemia, increased metabolism and nutrition with growth or destruction and necrosis.

When the circuit is continuous from cathode to anode it is said to be closed and when it is interrupted so that the current cannot flow it is said to

*Read before the Medical Society of Bay Ridge, N. Y.

be open. We close a switch to cause the current to flow and open it to stop the current. This is opposite to a valve or faucet. The higher the source of the water fall the greater the power; and likewise, the more potential difference between the two electrical states of positive and negative the greater will be the electromotive force. Water power may be measured in terms of waterfall height; electromotive force is measured in volts. The current is measured not in electrons but in amperes, just as we measure water not in drops but in gallons. And we speak of the current flow in terms of amperes per second. In medical usage milliamperes are found the more useful units. The total quantity of electricity delivered is measured in coulombs and is found by multiplying the number of amperes a second by the number of seconds during which the current flows. A milliampere flowing for one second delivers only one milcoulomb of electricity.

Now anything which obstructs the flow of the electrons is technically called resistance. Different substances offer different resistances to the passage of electrons. Those with the greatest are called poor conductors or insulators or dielectrics. Lengthening the circuit, decreasing the size of the conducting path, as making the wire smaller in diameter and introducing substances having great resistance, such for example as the dry skin, will reduce the quantity of current passing through the circuit and require a longer time or more voltage to obtain a given number of coulombs and the desired physiological effect. Resistance is measured in ohms.

The relation between electromotive force (measured in volts), the number of amperes in the current (expressed as ions) and the amount of resistance (expressed in ohms) is known as Ohm's law. One volt will force one ampere of current a second through a resistance of one ohm. To reduce the quantity of current we introduce resistance by means of a device called a rheostat. It is analogous to the valve in a pipe. When all of the resistance is thrown in we have no current. To increase the current when we increase the resistance, as when the body is placed in circuit, we increase the voltage. Poor connections between the apparatus and the rheophores (wire cords) or between them and the electrodes or between the electrodes and the body all increase the resistance. This is not desirable. We must have good conductivity by means of good contact at all junctions in the circuit. When resistance occurs the voltage is transmuted into heat, the degrees of heat being directly as the square of the amperage. This is Joule's law.

Every apparatus has a maximum of voltage and of milliamperage, beyond which you cannot go. This should be known. Every piece of apparatus has regulating buttons or sliding buttons with scales. The scales show usually the parts into which the total output of the machine as maximum may be divided for administration. The voltage and milliamperage given at any moment is disclosed by a voltmetre and a milliampere metre respectively. They are essentials to the amount of the dose.

When a patient is placed in the circuit with a direct, continuous current of electricity we notice certain effects in the tissues between the electrodes which are called the interpolar effects, and certain effects which are different and characteristic at each electrode called the polar effect. The polar effects are true of galvanism only.

To digress for a moment, we are all aware of the fact that living bodies consist mostly of fluids, flowing in channels and confined in cells. These fluids are mostly watery solutions of sugars and colloids or salts and bases. We know that the salts are electrolytes, that is will carry the electrical current by reason of the fact that they are always ionized in solutions according to certain invariable laws; we know that the degree of acidity and alkalinity are measurable chemically by optical standards and electrically in microvolts as hydroxyl and hydrogen ion concentration, the latter being made use of as a standard unit for comparison of the degree of acidity of body fluids.

We are sure that with moderate currents there are some interpolar nutritional effects due to heat generation according to Joule's law. Experiments of various sorts show that the chemical changes are appreciable only at the electrodes connected with the poles. If, however, our dose is increased in milliamperes or time beyond that which the tissues can pass and live, then we have an electrolytic effect which is due in part to chemical dissociation and in part to heat engendered by the resistance of the tissues to the current. The polar effects are chemical and thus physiological and pathological and they are characteristic for each pole.

The electrode attached to the positive pole attracts and liberates oxygen gas, acid radicles and the halogens from their compounds in the tissues and in solutions containing them. This pole is therefore always acid in reaction and will turn blue litmus paper red.

Acids coagulate albumen; hence, we have a shrinkage of tissues, clots are formed, hemorrhage and lymph oozing are checked and, if prolonged, a caustic necrosis results with consequent hard, firm scar. Positive electrodes will stick to mucous membrane. The acid condition is sedative to nerve endings and nerve tissue, which condition is called anelectrotonus. Bacteria are also killed, and putrefactive and necrotic conditions are rendered aseptic.

All i ns which seek the positive pole or anode are called anions from ἄνδ up and ἰὼν to travel, and, since unlike signs attract, they must be electronegative. This gives us the key to another fact, namely, that the nucleus of a cell staining with an acid dye must be electropositive.

Since like signs repel, metals and bases are separated electrolytically from their compounds in solution when applied upon electrodes attached to the positive pole and are driven into the tissues. This action is called iontophoresis. It is sometimes called cataphoresis or anaphoresis, which are meaningless terms, and ionization, which is something entirely different, and ionic medication, which should be iontic medication.

Lithium, zinc, copper, magnesium, silver, mercury, iron, and other metals, morphine, atropine, quinine and other alkaloidal radicles are separated as ions from their compounds with acid radicles and are driven into the tissues by the positive pole.

A two per cent. solution in water of the sulphate of the metals or a ten per cent. solution of the hydrochloride of the alkaloids is used.

We now know that none of these ions is driven far into the tissues and that the greatest effect is upon the surface where applied. The heavier ions are usually deposited in the skin as albuminates and the current is then carried by the lighter ions of the body juices, particularly the hydrogen ion. However, as the capillary stream rapidly carries off the lighter ions, in the case of the more powerful alkaloids for example, we may get systemic effects, but this is a poor way to administer drugs.

Zinc, copper and silver are germicidal and when added to the germicidal effect of the positive pole are doubly effective. Where reachable by these solutions or by means of copper or silver or zinc electrodes, all infective foci are readily sterilizable. Sinuses, boils and carbuncles, middle ear infections, especially if discharging, urethral and bladder infections, uterine and vaginal infections, pus tubes and prostatic inflammation, conjunctival, nasal and oral infections, ulcers and gangrenous conditions are amenable to this treatment.

The anodyne, or anelectrotonic effect makes this pole appropriate for neuralgias and neuritis. Its coagulant effect makes it indicated in bleeding from all accessible organs, as nose bleed, metrorrhagia and menorrhagia, especially when duè to fibroids, by the method of Apostoli. In cases of subinvolution and postpartum hemorrhage this pole is especially valuable. Neiswanger has also employed it with good effect in extrauterine pregnancy to destroy the product of conception. It is valuable in shrinking hydrocele and other cysts, as wens, nabothian gland cysts, and cystic goitre. Adenitis, whether tuberculous or chancroidal, especially after necrosis with fistulæ, is amenable to this pole. Magnesium ions have a particular applicability to warts and are also sedative. Lithium, sodium, potassium, magnesium, etc., are better given otherwise for systemic effect, as the amount administerable by electricity is inadequately small. Quinine ions have been found valuable in trigeminal neuralgia and herpes zoster, while zinc and mercury with an electrolytic current are valuable in malignant growths.

The electrocoagulation of the blood in aneurysmal sacs by means of many feet of fine copper, gold or silver wire introduced into the sac and used as the positive pole upon which the clot forms has been accomplished with partial success (1).

The contraindications for positive galvanism are scar and fibrous tissue, such as ankyloses and strictures and all conditions requiring softening and hyperemia or which are made worse by shrinking and where we do not desire the effect of the metallic and alkaloidal ions.

The electrode attached to the negative pole liberates hydrogen and forms hydroxyl, hence the reaction of the tissues is alkaline, the tissues are hydrated, softened and become hyperemic, hence swell and their nutrition is increased. The alkaline reaction is painful and stimulating, causing the condition of nerve reaction called catelectrotonus. Bleeding and oozing are favored and, if prolonged, a caustic colliquative necrosis results with a consequent soft, pliable scar. Bacterial growth is favored, scar tissue is softened and metals and alkaloids are separated from compounds in solution by this pole, while acid radicles and halogens are repelled, which is called anaphoresis.

All ions which seek the negative pole or cathode are called cathions, meaning cathode seekers, hence they are electropositive (unlike signs attract). The negative pole is therefore used to destroy tissue where we do not desire scarring, as in warts, moles, superfluous hair and nevus, or to soften scar tissue, as in strictures, lachrymal, esophageal, urethral or elsewhere; or in burns, Dupuytren's contracture and false ankyloses, or pterygium and corneal opacities. In infantile uterus it is valuable when combined with the galvanic sinusoidal, and for dysmenorrhea due to contracted os or adnexal adhesions or endometritis it has no substitute.

It is used to drive in iodine and chlorine, which are both antiseptic, while the latter is softening to tissue and the former is useful in goitres of adolescence and actinomycosis. The use of negative galvanism to a swollen breast will relieve a mastitis and so differentiate between a benign and a malignant condition. An inflammatory condition is made painful, while a noninflammatory condition is soothed.

The negative pole is contraindicated where there is hemorrhage or oozing or edema, or where we desire a firm, tough scar, or where we desire a shrinkage of tissue or the use of the anions for their medicinal or antiseptic effect. The use of the galvanic current for the relief of lead, silver or mercurial poisoning is without effect therapeutically. Iodine, however, will separate out at the positive pole when ingested as iodide by the mouth. This is much feebler than the opposite method of negative iontophoresis.

The dose in any case is determined first by the tolerance of the patient, as governed by the sensitiveness of the tissue traversed. A few milliamperes at the beginning of treatment usually increase during the treatment, as the skin becomes a better conductor when moist. Next, the time of treatment should be of sufficient duration to destroy all the pathological tissues at one session when electrolysis is used. This does not apply to removal of hair where only a few can be removed at a session. In other cases not less than fifteen minutes and in some cases even an hour may be necessary. The sessions should be spaced according to the degree of reaction—usually every other day—when treating pelvic conditions or strictures or scar tissue. It is best to begin with small doses, tolerable to the patient, five to ten ma. for five minutes and increasing cautiously. With inflammatory and purulent conditions, the time may be lengthened to thirty minutes or more and the treatments may be even twice in one day, as in carbuncles and boils.

IONTOPHORESIS

Shoemaker (2) says that the indications for iontophoresis are, 1, to produce local anesthesia for neuralgia, superficial pains and for cutaneous operations; 2, for topical medicamentation; 3, to facilitate absorption of medicines from baths; 4, for diagnostic purposes.

The subject of iontophoresis has for a long time

produced considerable literature, some of it valuable for its scientific quality, some of it valuable for its clinical results, without undertaking to evaluate the explanations attending the reports, and a great deal of it speculative and repetitional of previous faulty observations. A recent report (3) will give us possibly the most accurate résumé of this procedure. The protocols of their experiments are worthy of study.

They studied the following problems: The influence of the electrical current *per se*. The effect of similar applications of the drug without the current. The influence of the current in the absorption of metals. Likewise on the absorption of alkaloids and glucosides. Likewise upon the absorption of halogens, nonmetals and acids. Detoxication of the body by means of the electrical current. The treatment of infections by experimental electrolysis.

They discuss the pros and cons of medicamentation by iontophoresis as follows:

Pro.—The drugs are not subject to digestive changes as with oral administration. With hypodermic administration the drug follows the fluids and is quickly absorbed or excreted. The local effect is preponderant and is to be desired when it is not advisable for a systemic distribution of the drug. Larger quantities therefore can be applied locally and into the tissues than with external applications alone.

Contra.—The absorption of ions with the electric current is not satisfactory where systemic results are desired. The local effect of anesthetics is temporary and very superficial. The doses are variable, the application often disagreeable or painful and there is danger of caustic burns with slowly healing ulcers. Cataphoresis, implying an electrical osmosis or liquid flow from anode to cathode, is molecular rather than ionic, slow and is at present to be largely disregarded. They quote approvingly Clark's conclusions, which are: "The application of the galvanic current alone, without the use of remedial drugs, is often of benefit in various pathological conditions due to interpolar ionization of the tissue constituents, thereby altering nutrition, improving metabolism and producing stimulation or sedation, contraction or dilatation depending upon the polarity.

1. The electric current may be used to introduce ions into the skin. The transference depends upon the factors of amperage, voltage, resistance of the tissues, time and area of application, the chemical nature of the ion and its migrational velocity with the current. The heavy metals enter into insoluble and noniontic compounds in the vicinity of their port of entrance and give up their charges to other faster moving ions in the tissue fluids. Their effect is therefore purely local. They can be used for this effect only.

2. The electric current facilitates the introduction of many alkaloids through the skin. a. The physiological effects of strychnine and pilocarpine were obtained in rabbits after an hour. b. The physiological effect of caffeine and curare as gauged by systemic effects was nil after two hours. c. The action of curare, picrotoxine, strychnine, veratrine and nicotine was accelerated when introduced through the skin of live frogs. d. Using a current of two ma. for ten minutes, cocaine produced a moderate but incomplete anesthesia of the skin of a finger lasting an hour, procaine and butyn produced a mild anesthesia lasting about half an hour, while benzylcarbinol and salicin failed to produce any symptoms of anesthesia. 3. Halogens, nonmetals and acids vary in penetrability, some (CN_1) being accelerated, while others (NO_3, salicylic acid) are negative.

4. The theory of detoxication of poisonous ions by electrolysis is fallacious and not demonstrated, as they are of a slower moving class and readily superseded by the more rapid ions H, Na, Cl_2, I_2.

5. The release of nascent iodine at the positive pole in the tissues after ingestion of iodides may possibly be utilized in certain infections, but the ordinary electrical current produces changes sufficiently drastic, according to the pole employed, to give equally beneficial results."

W. J. Turrell (4), of Oxford, England, has also summed up the matter in a recent paper. He says that the therapeutic value of medicamentation by drug ions is nil and any therapeutic effect is entirely due to the well known physical action of the galvanic current. Drug or other ions are not carried into the tissues deeply, but only just beneath the skin. The claim that salicylic ions, for example, can be administered by galvanism into a joint with the opposite poles on either side of the joint is straining credulity to the breaking point and is not borne out on theoretical physical grounds nor by experiments which were supposed to prove that effect. "The method has nothing to recommend it in preference to the usual and more simple modes of oral administration, hypodermic injection and inunction." He attributes the interpolar effects, which others have ascribed to iontophoresis, to the heat engendered according to Joule's law. In this he is corroborated by Campbell (5), who goes further, however, and suggests that the beneficial effect is due to the stimulation at the electrodal poles. This would place the mustard plaster upon an equal plane with galvanism in its anodyne effects, which of course is not so.

Inchley (6) reports a series of experiments in iontophoresis. His summary is:

"1. Both positive and negative ions can be absorbed through the skin or mucous membrane by means of the electric current, if a solution of the drugs be applied at the appropriate pole.

2. The current is conveyed through the body by the tissue ions; after the introduction into the body of foreign ions the current has no further appreciable influence upon them."

To what are we to ascribe the effects which clinical observers have interpreted as due to the entrance of ions deliberately administered for specific effects? I believe we will be correct in not brushing aside as unscientific their observations because of apparently conflicting physical laws, but in believing that there is something which the physicist must not lose sight of, namely, that we are dealing with living tissues and that in some cases the administration locally by electricity of certain ions is not only more effective than by inunction, and that by way of the lymphatics and blood stream some of the finely divided ions lodge in selected tissues without trauma and more accurately than from hypodermic injection.

(*To be concluded*)

The Old Age Factor in Psychoanalytical Therapy*

SMITH ELY JELLIFFE, M. D.
New York

In the present communication no attempt is made to cover the entire ground of the suggested title. Such an effort could advantageously take up the entire pages of this issue. Even limiting the discussion to the presenium and the senium, as is here purposed, so many important issues are involved that a complete discussion is equally impossible.

In the first place one might attempt to outline what is meant by age. In a manner of speaking some individuals are old, i. e., worn out, almost at birth, and at the opposite pole of life, many an old one is still youthful. In other words, as Ward Crampton in recent years has quite interestingly pointed out, what the classical author of *De Senectute* has said some millenia before him, the chronological age of an individual is not a necessary index of his physiological age. And if one would reach out still further it may be stated that even physiological senescence is not an absolute criterion for psychological deterioration.

Thus the literati tell us that Conrad began his career at fifty, and tradition still tongues the anecdote that Gladstone started to learn Greek some ten years later. Whom the "gods love" may "still die young" and Mozart, Keats, Shelley and other names spring to the fore as illustrative of the early burning out of some men of genius, yet on the other hand many a chronological dotard has offered to the world surpassing spiritual gifts of enduring social value. To enumerate them is unnecessary.

The most orthodox old saw runs that "man is as old as his arteries," and the name of Osler has been widely traduced as saying that "sixty" is the proper chronological stadium for chloroforming. Taken all in all, whereas these generalized formulations have statistics on their side, upon a larger review one cannot refrain from the counter attack apropos of mathematical absolutes, that the three advancing categories, "Lies, damn lies, and statistics" more correctly states the actual truth when the individual himself comes for review.

From the viewpoint of behavior then the presenium and senium, physiologically, i. e., arteriosclerotically defined, offers many an interesting problem. From the aspect of understanding the underlying motives of conduct in individual cases of medical interest and how to deal with them therapeutically the vistas of interpretation have been enormously expanded and made more definite through the teachings which have come through psychoanalysis.

As already stated, no attempt will be made here to systematize and to present in strictly logical fashion the various nuances of the numerous questions of geriatric interest which are presented now to one, now to another practitioner. Still in order not to make this communication too general it may be worth while to partially attempt to make some dividing lines between the more "normal" and more "abnormal" manifestations which may be met with in medical practice, accentuating the conviction that normal and abnormal are only convenient fictions forced upon us by practical expediencies.

As already foreshadowed the chief accent is here to be laid upon psychologically understandable modifications of behavior.

Advancing age brings with it its inevitable decline. This is the law of life that advances to death, from which no living organism, from amœba to homo, can escape. *Bios,* the old Greek word, meant both life and death; in which we see repeated throughout the evolutionary scheme of things attraction and repulsion in physics, positive and negative in chemistry, pain and pleasure in sensation, sickness and health in medicine, good and bad in ethics, and comedy and tragedy to the universal onlooker, call "it" by any name one will—God, Fate, or *Das Es.*

Psychology in its largest vision, offers some interpretative formulæ as to how human beings behave in view of this inevitableness, and this is the theme into which the present paper would enter in but a fragmentary way.

Almost every one of the younger generation has an underlying intuitive insight into the many excuses (rationalizations is the more scientific phrasing) made by the gradually older growing individual to account for his loss of grip upon reality. Whether such loss of grasp fall within the sympathetically explained "he is getting old" or passes over into the belief that the old man must be "junked" as a "psychotic," it is only a question of degree. And running true to the biological differentiation of "selfpreservation" instinctive activities, or the still more tension laden "propagation of the race" thrusts, abnormal behavioristic reactions in the aging show themselves as "compensatory" reactions in the "economic" or the "sexual" sphere.

To illustrate let us take two examples which I have been asked to adjudicate; briefly presented, as formulæ only.

Case I.—A man, sixty-two years of age. He had been a "boiler maker" all of his life and had been fairly competent up to two years before the specific situation. For reasons, too detailed to narrate, he had regressed to the level of a night watchman on the river front in the employ of a large corporation. One night he stumbled and fell upon an incoming vessel and sustained a trifling injury, somatically speaking. Shortly thereafter he was discharged since the evidence was incontrovertible he was not up to his job. Psychologically, however, his reaction was that he had been given a "dirty deal," and since the natural cupidity of his surrounding media, wife, sons, etc., supported him, a medicolegal proceeding was inaugurated to show that the injury sustained—trifling abrasions of the body—was the cause of his incompetency. He himself reacted by an excessive exploitation of the injustice dealt to him in his discharge. He dissolved in tears, emo-

*Read before the New York Neurological Society, December 2, 1924.

tionally overwhelmed by the cruelty of the corporation, and had for months sat in his chair at home, a typical picture of an "arteriosclerotic dement with compensatory paranoid ideas." As a matter of fact the injury sustained was not a competent producing cause (medicolegal requirement phrasing) of the clinical picture presented, yet this was one of the type of situations upon which the "expert," presumably myself, was called upon to decide and adjust the relative merits of the situation.

Psychoanalytically speaking the situation is quite clear, for psychoanalysis has a clearer understanding of the "selfpreservation" instinctive ego than the usual judgment of the proletariat. The two years earlier regression to the "night watchman" level is, for the neurologist, satisfactory evidence of the essential deterioration of the individual. The accident, however, is made (chiefly by the instinct of selfpreservation, the libido situation cannot be entered into here) the causative crucial point of departure from the level of efficiency. Further comment is unnecessary save that this kind of presenile and senile reaction is extremely widespread.

So much for the ego component—selfpreservation, economic aspect in a specific instance.

Now let us turn to an ambivalent (i. e., bipolar situation), also in the medico legal sphere.

Case II.—A young woman made a complaint to a policeman in the Grand Central Station that an old man of seventy, sitting by her side, with outspread encompassing newspaper as a shield, nudged her, and as she turned in response, she saw his penis revealed, erect or semideclining; who could say relative to her knowledge as to its tension. The old man was arrested and his case called for an "expert opinion."

Here the problem falls within a different category, into the intricacies of which we cannot now enter. Pathological exhibitionism is the nosological group into which the case falls. It is immaterial here to give the statistics of this type of abnormal behavior which must be dealt with by the district attorney in New York or other large city. We are, for the moment, only interested in the psychoanalytical interpretation of this type of behavior.

In the study of the present instance we have an old offender and Bellevue and the Manhattan State Hospital, more or less, sociologically speaking, adequately deals with him, but for our present discussion, the obvious outstanding dereliction is but an exaggerated example of a vast medley of similar situations varying from the palace to the hovel, to which the "innocent female" is exposed.

How does the psychoanalyst deal with these situations, first as an agent of society, and secondly as an interpreter of the instinctive impulses of the individual? In the role of an agent of society he must condemn the sick individual, not to Sing Sing, but to the Manhattan State Hospital; but secondly, he is scientifically (sociologically conserving) curious as to the specific causes of the individual's behavior. From this aspect he may find many ameliorating circumstances, in so far as he may discover, and indeed did unearth, compulsive factors dating from early childhood, which forced him to the conclusion that this type of conduct was not wittingly vicious, but unconsciously compelling. This enabled him to say the patient's behavior was psychotic and sick and not "criminal"—according to the legal definition.

But these are questions which less frequently come within the sphere of the general practitioner, furthermore they lie somewhat aside from the title of the present paper, for they are so quickly transferred to the social legal machinery that, as introduced, they should be thrust aside, in order to get to the real issues here contemplated.

The essential issue then is what kind of neurotic or psychotic behavior can be advantageously treated by the generally understood method of psychoanalysis. From this point of view, in reality, a host of situations arise, less dramatic, less tragic, perhaps, but still quite compelling, but actually representing in attenuated forms the sample cases already cited.

In the earlier years of the development of psychoanalysis, the neuroses and psychoneuroses were thought to be the special fields for the applicability of the generalizations with which Freud has made us familiar, but as time went on it developed that a general philosophy of life and its interpretations lay behind the principles so conscientiously worked out by Freud. The unconscious, long ago felt as a force underlying instinctive behavior, now came under the scalpel of specific dissection and it soon became evident that the human being really was worthy of the Nobel prize for his superior gift of "passing the buck" to himself.

Psychopathology gives the general term "rationalization" to this process and it distinguishes a great variety of grades in it. Some of it is undoubtedly physiological—for certainly if man did not have a swift cocksure answer to things, but had to inquire into the underlying "isness of the is," he could not function. Much of the stuff fed us from the cradle to the grave as education, knowledge, logic, is a crazy patchwork of these fictions, but inasmuch as they constitute the particular gilded small coin of the masses it passes muster and is serviceable in the turmoil of life. When pathological rationalizations commence to influence behavior in a manner inimical to the patient's own comfort or that of his surroundings then the problem arises how to get at these inner factors and relieve them. (4)

It is no longer necessary to attempt to boost psychoanalysis competently utilized. I listened to lectures in my medical course upon healthy laudable pus and was told that Lister was a fanatic and that antisepsis was a passing fad. And many are the pseudoprophets who have been talking the same kind of stuff for the past twenty years about Freud and psychoanalysis. There are still even today incompetent surgeons after all the years of technic, and surgical technic is crude plumbing compared to psychoanalytical technic. Still with the many great advances in psychoanalytical technic the question has become more and important as to its availability in dealing with the special medical problems of those of advancing years.

It may be recalled that Freud (1) himself raised this question early and very tentatively showed the difficulties. Whereas it is known that youth, intelligence, a certain amount of character, etc., permit one to give a better promise of help for the psycho-

neuroses, yet as has already been pointed out chronological, physiological and psychological age do not go hand in hand .Moreover the technical advances since then are offering more and more to the psychoanalytically thinking physician and the old age factor is becoming less and less formidable. Historically Abraham's paper (2) in 1920 upon the same subject is worthy of citation in that he comes to similar conclusions and cites some illustrative material, particularly emphasizing its value in the treatment of various depressed states of advanced years. He also reports an excellent result in an old compulsion neurosis. And a number of others. Abraham also speaks of failures as well and with our advancing ideas concerning the reasons for the neurotic symptoms, psychoneuroses, psychoses and unconscious psychological factors in organic disease it can readily be seen why in certain cases no success will crown the most sincere and intelligent technic.

Other communications on the subject are scanty in the literature although published case histories often show that the patients are advanced in years.

Like Abraham I have had my successes and failures and can say that I have learned caution relative to prognosis. At one time I was even as brave as a lion in the belief that "some acquaintance with the patient's unconscious would be of benefit to him in the treatment of his annoying symptoms." Now I am much more inclined to tell my older patients that disease symptoms, physical often as well as psychical, are for the most part intuitively found compensations for inner character defects; that if psychoanalytical principles be rigorously applied their most cherished beliefs and fundamental philosophies, and their consequent emotional valuations will be quite profoundly stirred and they will not like it; that they will probably curse me out and call me a quack or a shyster, but if they have real guts and can look themselves fairly and firmly in the face then much can be done for them.

Case III.—I recall being called in consultation by a colleague in this case. The patient, seventy-two years of age, had a partial motor aphasia and slight hemiplegia which had evidently been occasioned by a cerebral softening. The usual advice, etc., was given and after the acute situation had gone by some few months his physician sent him to me to be looked over.

He still had a residual difficulty in finding his words, his hemiplegia had cleared up save for slight weakness, but he was anxious to know how to live. He had had a slightly similar attack a few years previously and he partly shared the superstition, of "three out all out."

And so I talked with him from the psychoanalytical point of view. It soon was learned that during the past four or five years he had been getting increasingly violently angry; was more and more irritable and often these explosions left him all in, and the "chronic chip on the shoulder" that he carried everywhere with him got no relief from golf, or motoring, or business, or anything. He was still an active, forceful personality and we had to overhaul the whole works—which we did. He was securely well to do, hence the "selfpreservation" aspects of his instinctive life were not primarily involved; but it soon developed how he was handling in an imperfect manner a declining ability to have intercourse from nonerection, although harrassed by augmenting eroticism. This is a frequent situation in older men and when made widowers in the sixties the various clinical pictures resulting are very distressing for the patient and baffling for the physician.

In the present instance we had increasing irritability, increased blood pressure, violent outbursts—psychical, and a couple of blowouts—arterial.

That which was playing on the eroticism was an old daughter complex component. Her relations with the father were very cordial and pleasant, but she was not as wise as she might have been in periodically permitting him to get a glimpse of a difficult marital situation with herself. Every time this was brought up, he was extremely kind and helpful—gave her advice, comfort, and even money—but it soon became evident that he repressed a hatred to the son in law and "wanted" the daughter, and the response was an attack of temper—displaced over to the wife and an increase in the eroticism which by reason of the outburst on the wife found no way of satisfying itself—hence an increasing sense of frustration.

This is but a short thumbnail outline of a complex situation to which the old man caught on and soon established a better rapport with the wife, regained satisfactory relations, had it out with the son in law and got a good adjustment there; helped him over a hard bump which he had not wanted to tell the wife—eased up her friction somewhat and a much better working combination was established. He is now eighty and busy still and has had no further blowouts to date.

Having studied in great detail the fundamental psychical pathology in a patient with persistent high blood pressure, vascular crises and nephritic blowout (3) I am certain that 'psychoanalysis has a great future in straightening out some cases of this type where the internal dynamic tensions are not as great as in the case studied, and hence are better able to be managed. I feel certain that this type of understanding, which will come to be the general heritage of the profession, will be a most helpful adjunct to or substitution for present dietetic and pharmacotherapeutic procedures.

Another type of case more within the narrower neuropsychiatric frame is also thumb sketched.

Case IV.—A single woman, fifty-five years of age, stout and old fashioned came into the office all bundled up including several wraps of thick veiling over the face. True it was in January and the weather chilly but not cold. She was timid, deprecatory and sought to hide herself from observation. She was anxious, restless and emotional. She did not want to remove her veil as "her nose was so disfigured"; there were cracking noises in it. She could not keep her feet quiet, there were vibrations going on in them; her heart was palpitating at a rapid rate—124—and she had very unpleasant contractions going on, in what I learned later were her "privates."

I learned partly from her, and partly from a very petite, slim, and attractive gentlelady, a cousin of hers, seven or eight years younger, who had looked after her for the past seven years since she had been

incapacitated, and who had practically supported her for seventeen years, that about seven years before this she had had what the doctors called a nervous breakdown (menopause neurosis—two years preceding actual cessation of menstruation).

She became intensely nervous and depressed, had persistent insomnia, some loss of weight—from a previous 190 to 175 pounds (in younger days she weighed 120 to 130)—severe palpitations, especially at times at night she would wake up from nightmares with this rapid heart action, rush of blood to the head, a sick nauseous feeling in the back. But the feeling that drove her to a sanitarium at this time—seven years previously—was the unhappy depressing thought that the head and especially the nose was swelling and was growing so large that she had become an ugly old being and that everybody was looking at it. She thus was unable to travel anywhere, unless heavily veiled and had begun to be a recluse, more and more confined to her home, or to the immediate circle of her intimates.

She remained in the sanitarium the better part of a year with but little change in her condition save that with the help of bromides and other narcotics she slept much better. She had a great deal of skin irritation from the bromides and the itching became quite acute about the genitals which at times became red, swollen and eczematous.

She then led an extremely restricted life for the next six years with ups and downs. She was never quite as depressed for as protracted a period, but she continued to feel the palpitations, rush of blood to the head, irregular sleep with nightmares, the clutching sensations at the heart, and above all the persistent compulsive idea of the larger growing nose that prevented her going anywhere.

She lived with her cousin, all of this time doing some of the housework, but was a chronic invalid, attended and cared for by the selfsacrificing and classical type of New England selfeffacing sympathetic cousin. She read a good deal—in her books alone could she become absorbed and lose herself.

She came to consult me because of a growing intensity of the vaginal contractions which had been added to the general picture some six or seven months previously, and an increased intensity in the annoyance she felt about the nose being the object of everyone's attention. This obsessional thought was uppermost in her mind and unless heavily veiled she could not travel in the subway, which was the most direct and only feasible way to come to my office.

After several interviews it was clear that the patient had since childhood been "nervous" and that the nose obsession had begun as far back as her fifteenth or sixteenth year, when she first began to menstruate. She recalled that at that time she used to watch people's faces a great deal, and in looking at her own face in a mirror, which she did frequently, she noticed a white spot on the nose, and was much concerned about it. It was not acute, however. Again at twenty she had a period when she thought it swollen and was growing larger. While cooking in the kitchen the idea would be more persistent. "She always had admired pretty noses." "She liked dainty features—hated coarse features." There were a series of recurrent compulsive thinking periods in which the nose was a prominent feature, and there were other episodes of a general anxiety hysteria character all throughout an extremely difficult and complicated life history.

This life history is too complex and varied to detail and only a few salient features need accenting. Her father, a visionary son of a previously well to do family, who had gone west to make a fortune in gold mines, died when she was eleven. Her mother had left her father when the patient was but seven years of age. She was then cared for by grandparents, and aunts and then by the uncle, father of her present friend. This uncle had been one of the trustees in a considerable estate. She had lived in several states of the Union in all of this going and coming, had never had a settled abode save as housekeeper for her uncle, and mother to the little cousin until she was about eighteen. The uncle had discouraged all male friends and finally she had come east with the cousin after the uncle's death. This same cousin having the much diminished residue of the whole family estate which had been the object of untold bickering, expensive litigation and heartaches of the well known character.

The patient rather quickly established a type of childish clinging transference, wrote frequent notes of questions, and dreamed abundant dreams of a very simple nature. Thus were shortly established many of the well recognized individual factors of the pregenital organizations of the libido. Very soon there came up for discussion the influence of early masturbatory activities. These started at four or five years of age and were of the not infrequent seduction type where little boys and girls showed the usual curiosities. Thus when but five years old, in bed with a little boy one year older, who tickled her genitals and made them all hot, she recalls she got up and poured cold water over them to relieve the itching. To these were added quite early cunni linguis attacks, from a French teacher who wanted her to kiss her genitals; she was only five or six at the time. Thus were emphasized the early foundations of the intense genital itching which followed masturbatory repression at eighteen to twenty and which was related to the resultant frequently recurring, throbbing sensations and swellings in the genitals, which were a cardinal feature of the vaginal contractions of which she complained when I was first consulted. There were a number of overdetermining factors which the early dreams brought in the associated material.

Thus to quote a dream which occurred on the fifth interview:

I dreamed I was going through a long narrow passage. It was stony, like marble and carved on the sides. Away ahead there was an opening and walking towards it there were four—five, just see them, five images. A woman was standing there. She was young and thin, she had a grayish turban of fur and a muff, all covered in a misty gray, as it were. I knew it was myself and as I got nearer to her, I woke up—"With terrific palpitations of the heart."

To the practised analyst this dream shows the masturbatory features, and the associations turned up the early, French teacher; it was she, all dressed in furs, who had started the cunni linguis phantasies,

and other associations detailed the early troubled life of the father and mother, the quarrels and separation; ("her mother was not a good woman"), her life with her father, and boarding school (seven-nine) where there were other genital attacks. Also at nine-ten when in a western hotel she exhibited her genitals at the window and she was able to recall the childish delight at having the people in the street look at her. Her father's death when she was eleven, his parting messages to her—his little gifts (which she still cherishes). (A determinant for her childish transference to me.) Her life with her grandparents.

Were it not a commonplace of psychoanalytical revelation I could give in great detail the many infantile and adolescent reminiscences all bearing upon the peeping and exhibitionistic activities, and the later arriving masturbatory and still later seduction phantasies which were the determiners for much of the anxiety hysteria displacements so prominent throughout her harried life. Of these her marked selfconsciousness, timidity, docility, blushing, cardiac palpitations (so marked in her insomnia and nightmares) were evident consequences.

In her transfer situation she finally could exhibit to her heart's content without the sense of guilt and it was quite understandable how some of the annoying genital symptoms were markedly relieved within a month or two after analytical therapy.

But the nose situation still remained as persistent or more so for some time. Resistances concerning this overdetermined factor were quite evident. *"She dreamed she had a dream"* and its related repressed material was characteristic of the period which partly gave way when the more recent "nose" phobophilic determiners slowly came into prominence.

One striking incident came out after six weeks. She recalled that she was suffering from a mild diarrhea—this was just before the sanitarium period. She had used up all of the toilet paper and had recourse to a bit of newspaper. She also had a bad cold at the time and had used up all of her handkerchiefs. She wiped her nose with a piece of newspaper. Suddenly she felt that the ink had been transferred to her nose and in a terrible anxiety, with splitting headache and palpitation, she began vigorously to clean her nose from the supposedly transferred ink. On further analysis this revealed the well known displaced, anal-nasal, relationship and this started our analysis of the anal-erotic pregenital organization of the libido.

As I am not writing a *Jean Christophe* analysis of this patient, although the material is at hand, I will but briefly summarize what came out of some two years' more work. My patient could not come as often as I would have liked, they were really poor people and overconscientious and would not accept from me so much time for which they felt the recompense was trifling.

The nose symptom really was determined by the anal-erotic sadistic wish—unconscious of course—for the death of her benefactress cousin. The mass of detail regarding the economic-money-situation, the big estate, her father's flighty efforts in gold mining—the uncle trusteeship—phantasied as stealing her inheritance and its transfer to her cousin. Her envy and ambivalent love for the cousin, etc., these were long distance stations in the progressive development of the love-hate relationship to the protecting cousin.

Very briefly, she came to accept the revelations of her own unconscious, and after four years, there were about fourteen months of analysis in all, she became practically well.

At least sufficiently so as to justify me in the belief that a long chronic disabling psychoneurosis, with even psychotic developments of seven years' severe duration and a whole life time of compulsive-phobic ideation might be resolved by the psychoanalytical technic. All the more is this belief made emphatic since a large number of the socalled menopause neuroses have been so much more satisfactorily treated than by older methods employed by myself for twenty years.

And now a very brief but, to me, most interesting sequel of four hours of talk based upon a psychoanalytical background which savors of the miraculous, but be it what it may be, here are the facts known to me. There may be a multitude of others but I know only these.

Case V.—A brakeman on the Portland Oregon Railroad came into my office, why I never learned. He was fifty-six years of age. In very direct simple language he told me that for about ten years he had had every month a recurrent attack of intense depression, which lasted for three or four days. During this time he attended to his work with the greatest difficulty, invariably thought of suicide and had a host of guilty feelings.

These guilty feelings chiefly centred themselves upon three situations: his relation with prostitutes or degraded women, adolescent and manhood masturbation, and boyhood bestiality, he having attempted or accomplished intercourse with a calf in his later boyhood.

Careful anamnesis revealed that the periods of depression began approximately a month after his mother's death. He was single, she a widow for a number of years, and he had supported and lived with her some years after the father's death, due to a railroad accident. Still further anamnesis revealed that the attacks came on every twenty-eight days and lasted three or four days only, and careful inquiry and but a few fragments of unconscious material—dreams—showed that he was reliving, as a substitute for a mother attachment, *her* menstrual epochs, which lasted three or four days and had been characterized by periods of intense depression.

This mother identification, the Œdipus situation, the time period, and the unconscious situation being carefully gone into, after four talks the patient left me.

Two years later I received a letter from him saying that he thought he understood the whole business. He had not had another period of depression and was perfectly well. Whether it is all true or not I am not in a position to say. I present it as a cameo for the inspection of anyone interested.

It would of course be very gratifying if all situations might be as happily resolved as this one. It is the only one of like nature in my thirty years of experience, at least as occuring in an individual of advanced years. I have had some amusing and interesting experiences of quite striking results in

younger individuals, but this is my one banner case in an individual over fifty years of age.

Turning to the reverse side of the shield, however, I am in honor bound to state that, in general, with the aged, my failures have been greater than my successes. I could write of a number of cases in which I have felt that the psychoanalytical technic has given me no results at all in those over fifty years of age. Still while making this confession of impotency, as these are thumbed over on my record sheets, my faith in the real efficacy of the involved principles is not seriously shaken, for each and every case shows very clear indications why a real self revelation on the part of the patient could not possibly be conceived of by them as advantageous. In other words, the neurosis or psychosis was a better solution of their life difficulties than any that I, as an agent of reality, could offer.

Bergson in his delightful work on *Time and Free Will* (p. 9), has written the following:

"What makes hope such an intense pleasure is the fact that the future, which we dispose of to our liking, appears to us at the same time under a multitude of forms, equally attractive and equally possible. Even if the most coveted of these becomes realized, it will be necessary to give up the others, and we shall have lost a great deal. The idea of the future, pregnant with an infinity of possibilities, is thus more fruitful than the future itself, and this is why we find more charm in hope than in possession, in dreams than in reality."

This aspect of wish fulfilling phantasy, replacing reality, is not exclusively the field in which the aged revel—we see it often enough in youth—dementia precox for example—but when the problem arises in individual cases who have come through a fairly successful youth and who have reached adult years, and then commence to regress to phantasy formations, how far can the reality principle—as urgently insisted upon by psychoanalysis—be made applicable, based upon the experience just noted, mature judgment comes to a mixed expression. One can never tell. It is at least worth trying. Pessimism certainly closes the door—optimism, even if an illusion, is worth the effort.

Instructive Cases of Bile Tract Disease Considered Surgically*

WALTER L. BARBER, JR., M.D., F.A.C.S.
Waterbury, Connecticut

In going over my recent record of bile tract cases, I have selected six which were most instructive to me. I will briefly bring to your attention the points which seem worth reviewing.

CASE I.—Marian F., aged sixteen; entered my service in January, 1924, complaining of pain in upper abdomen with vomiting after every meal. Her earlier voluminous history had been: pain in left hip and leg, which was diagnosed as early tuberculosis of hip joint; plaster case applied, which she wore for eighteen months. Later her tonsils and adenoids were removed. During the following year she had had rheumatic pains in various places. Appendectomy in January, 1922; at this time the gallbladder was reported as negative. Six months later a low grade staphylococcus infection appeared in the lower angle of the incision, which persisted in spite of all treatment over a period of six months. When this healed she had other similar lesions over the body. During the latter part of 1923 there were several attacks of apparent cholecystitis, with no jaundice, no chill, and no fever. Upon her admission now to the hospital, the most troublesome feature was vomiting of all foods, with an occasional attack of pain over the gallbladder region. X rays showed no stones in the gallbladder, but a deformed duodenal cap and immobility of duodeneum which was probably due to adhesions to the gallbladder. On opening the peritoneum there was a mass of adhesions, binding the gastrohepatic omentum, the stomach, the duodeneum, and hepatic flexure tightly together. Carefully freeing these, the gallbladder was found almost unrecognizable, a mere cicatrix; there were no palpable stones in any of the ducts; cholecystectomy was done. Convalescence was normal and the wound healed primarily.

The patient today, ten months later, is eating and digesting her food normally, and is free from any further similar infection.

CASE II.—Mrs. M. H., aged fifty-eight years, entered the hospital on crutches, on January 5, 1921, complaining of severe pain in the back, extending down the left leg and thigh. Her earlier history showed that she had suffered more or less from rheumatic pains in several joints for the past ten years, always more persistent in the left hip. There had been occasional bilious attacks which were relieved by sodium bicarbonate and catharsis. For the past six months, she had become almost an invalid.

At the hospital the diagnosis of sacroiliac strain was made in the orthopedic service, and a cast applied. Two days later she had a severe attack of sharp, colicky pain in the right upper epigastrium

*Read before the New Haven County Medical Society, October 30, 1924.

accompanied by vomiting. This was relieved only by morphine. Temperature was 102°, and jaundice appeared in two days. Examination revealed resistance in the right epigastrium with a definite point of tenderness in the right costal arch. Diagnosis of cholecystitis was made. The cast was removed and after waiting for the acute attack to subside, which I believe is always wise, operation was performed. The gallbladder was found to be atrophied, white in color, with unusually thin walls. It was full of stones, one in cystic duct. Common and hepatic ducts were free of stones to palpation. Pancreas was somewhat enlarged. Cholecystectomy was performed. Convalescence was normal. Two weeks later the patient was moving about in bed and suffered little or no discomfort from her left hip. At the end of the third week she was up, out of bed, and bearing her weight upon her leg, without pain. March 1st, the patient was discharged, without her crutches. The result was spectacular.

I have been able to keep in touch with this patient and she has remained perfectly well ever since.

COMMENT

There is nothing unusual in these cases, but they emphasize so splendidly the gallbladder as a site of focalization. The teeth and tonsils are now commonly thought of and with these sites ruled out, the appendix probably is the next organ for consideration, with the gallbladder last. When the gallbladder is once infected, it seems to have little resistance in the future, and easily becomes the nest for bacteria. In both these cases, the gallbladder had been diseased evidently for a long time. In Case I, the gallbladder was not alone a hopelessly diseased organ, but by its inflammation, had created a dilated duodeneum, which could not possibly functionate properly. This patient had had her appendix removed two years previously, at which time the gallbladder was reported negative. Personally, I am inclined to believe that even then, the gallbladder was diseased and passed unrecognized. (I did this appendectomy.) To diagnose a diseased gallbladder in the earliest stages of its disease is of great importance. I believe we must do more than feel for stones, or for adhesions, or test the patency of its duct. We must examine its color, its mural thickness, and especially as Sir Berkeley Moynihan teaches us, look for that subserous deposit of fat found usually near its pelvis, or near the cystic duct, which is the first visible sign from the exterior of an infection of the walls of the gallbladder from within. Such cases as these prove conclusively that we must routinely make earlier diagnosis of our sites of focalization, before destruction of healthy tissue, with months of suffering for the patient.

Case III.—Mr. C. W., aged fifty-one years, seemed to present a case of typical chronic cholecystitis. His dyspeptic symptoms, bizarre in character, his chronic rheumatic features and the pain and tenderness located over the gallbladder region with some muscular resistance, are all typical.

November 9, 1923, at 3:00 a. m., I was called to his home. He had just walked up the stairs to the fourth floor when he was taken with the most severe pain, stabbing in character, located behind the sternum. There was no radiation except to the back. This apparently had been precipitated by the effort of climbing the stairs. He was in shock; face pale and cyanotic, and bathed in cold perspiration; respiration shallow, pulse thready, facies of extreme suffering. He could not lie quietly, but was tossing about the bed. There was still no evidence of cardiac disease. The abdomen was decidedly rigid, and whether this rigidity was due to muscular effort in attempting to relieve the spasm, or to some intraabdominal catastrophe, I could not make out. The extreme restlessness was typical of colic instead of a rupture of a viscera, in which condition the patient lies absolutely motionless, with no attempt to move. I was most anxious, fearing that I had allowed this man to go too long without surgical aid. Several hours later the tale was told. The heart, fatigued, began to dilate. The abdominal spasm lessened. The blood pressure fell, and now the abdomen showed no rigidity, no spasm, no distention. The patient died in the hospital twenty-three days later.

I regret that there was no autopsy obtainable, and that we do not know more accurately whether there was an existing cholecystitis, but the case certainly served as a great lesson in differential diagnosis. Of interest in conjunction with this case is the report from the Mayo clinic of eighty-six autopsies, in which coronary sclerosis was found with a complicating diseased gallbladder in twenty-four per cent.

Case IV.—The next case was that of Mrs. W., aged sixty-one, a farmer's wife, mother of four children. For years she had had gastric disturbances, and had to refrain from eating many articles of food on account of distress and vomiting. For past five months, these attacks had been more frequent, the pain always in right upper epigastrium with no radiation. A moderate degree of jaundice would follow these attacks after two or three days.

Physical examination was practically negative, except for a point of tenderness over the gallbladder region. There was no urinary sugar or blood sugar present. X ray showed no shadows suspicious of stones, but duodenum had limited mobility, probably due to adhesions.

At operation the gallbladder was found atrophied and bound down fast to liver, full of small, putty-like stones, one in cystic duct, easily dislodged. Common and hepatic ducts, not obstructed, as far as palpation could determine. Both pancreas and liver enlarged; appendix kinked and adhered to cecum. Cholecystectomy and appendectomy constituted the operative procedure.

The patient was out of bed in fourteen days, having had a normal convalescence. The next day, however, the patient suddenly complained of very sharp, colicky pains in the epigastric region, extending over across to the left side. Six hours later she vomited and the dressing was found saturated with a yellowish green bile which appeared from the sinus where the tube had originally been inserted; the pain being almost instantly relieved. Forty-eight hours later there was another, similar attack of pain, which was relieved, following a profuse biliary discharge. During the next week there was general improvement in the patient's physical condition, and patient was discharged at her own request, although plainly told that she must expect more trouble.

Ten days later she was readmitted to the hospital

in profound shock and collapse; had been vomiting almost continuously for the past three days. The abdomen was distended, and generally tender in the upper portion; pulse 140, respirations 36. No operative measures could be thought of in her present condition. Shock measures were ordered. Urinary sugar was present, and blood sugar, 212 milligrams. The patient was given small doses of insulin, with glucose. In twenty-four hours, the blood sugar was 192 milligrams; and the stomach began to quiet down; her mental condition appeared better; bowels moved well, and biliary drainage lessened. A few days later there was no discharge, and soon the sinus closed entirely. Within three weeks the patient was discharged in good condition, with still a slight increase of blood sugar, however. Today, the patient is well and is doing her regular household work.

It does seem as if insulin did just take us over a critical period and help to establish the patient's carbohydrate tolerance, and should always be considered in cases of pancreatitis.

COMMENT

I am not satisfied to dismiss this interesting case without a little reflection upon what was the probable cause of this stormy postoperative convalescence. I believe all of us see quite frequently during the early stages, attacks of mild colic, which we are likely to attribute to errors in diet, but which Charles H. Mayo tells us are probably the passage of mucus and sloughs, the last signs of an abating infection in the hepatic and pancreatic tissues. This was certainly more severe than one of these attacks; it was an intermittent biliary colic—the sudden rapid dilatation of a duct with its acute pain. Was it calculous or noncalculous, and if calculous, was the stone in the common or hepatic duct, and if noncalculous, was it due to an injury of the common duct at operation, or to a most severe inflammatory process in the pancreas or liver? Such was my quandary. The obstruction has now spontaneously cleared up.

In an article by Judd and Bruden, of the Mayo Clinic, I was especially interested in the finding at the second operation of twenty-four cases of intermittent biliary colic following cholecystectomy. In these cases there was no stone in the common or hepatic ducts; the most important and common lesion was chronic pancreatitis; not the hard interstitial type, nor the malignant type, but a chronic inflammatory type of infection of both liver and pancreas.

CASE V.—M. S., aged fifty-two years, a laborer, a moderate drinker, entered my service at the hospital January 14, 1922. He had always been well until a year ago, when he first began having indigestion off and on, with distress and fullness after eating. Of late he had felt weak, and unable to do his work, and had lost his appetite. One month ago, for the first time, he noticed jaundice which was now getting deeper and deeper until he was almost of a green color. There was little or no pain although tenderness in right upper quadrant.

The patient was of fair nutrition; his entire body was deeply jaundiced, with sclera deep green. Everything negative except a small mass the size of an orange, above the umbilicus. This mass was dull to percussion; and not tender to palpation. The liver was enlarged. Gastrointestinal series negative; x ray showed no shadows to interpret as gallstones. Urine examination revealed bile plus 4 with trace of albumin; Wassermann negative, bleeding time five minutes. Preliminary diagnosis, probably malignancy of pancreas. A blood transfusion was given the day before operation, with improvement in bleeding time.

Upon opening the peritoneum the gallbladder was found distended—much elongated with walls thin, containing no stones. The ducts showed no obstruction to palpation. The head of the pancreas was enlarged, hard and nodular. There were also some palpable lymphatic glands along the ducts. I felt we were dealing with malignancy. As regards the surgical procedure, certainly there must be biliary drainage, and this probably for a long continued time, if the patient lived. A cholecystoduodenostomy seemed to be the procedure of choice, as the cystic duct was free and gallbladder not badly diseased.

For the first few days the patient did well. He had no vomiting, no distention and no signs of tenderness. On the fifth day the intern's attention was called to some oozing on the dressing. This was the start. There was more oozing at the site of incision, subcutaneous hemorrhages elsewhere, and hematuria and hematemesis. Temperature went to 103° and then to 106° just previous to death.

COMMENT

In this case, it is probable that the bile did not start to flow but remained obstructed, and that the bile in the blood caused the capillary bleeding and finally the renal insufficiency, with death. The bleeding time had been reduced to four minutes and we thought we were safe in attempting operation. The case shows how important it is, that whatever the obstruction to the biliary flow may be, it must be very shortly relieved after operation and reestablished, or hemorrhage and death will surely follow.

CASE VI.—Mrs. S., aged fifty-two, had consulted me a number of times. Her complaint was chiefly indigestion with gas and belching; nausea and vomiting. These attacks began nine years ago; would occur at irregular intervals and confine her to the house for two or three days. She had never been pregnant. Early in life she had had typhoid fever and had suffered much from toxic rheumatic pains in various areas. In December, 1921, the patient suffered one of these attacks, more severe than its predecessors.

Vomiting was almost continuous and in four days was followed by jaundice, which increased in severity to a lemon yellow tint. The patient was losing strength and weight (twenty pounds) and showing signs of prostration. Physically, everything was negative, except some resistance and tenderness upon deep palpation over the gallbladder region. Clinically, urine showed bile plus 4; otherwise negative; coagulation time, ten minutes; Wassermann negative, (although as we know, a jaundiced blood often gives a positive Wassermann) test meal, negative; x ray, no shadows of stones, or any alteration in duodenal cap. Patient was not in bad condition but was given the usual preoperative treatment for

jaundice; not a transfusion, however. Tentative diagnosis, chronic pancreatitis with a possible malignancy.

At operation the gallbladder was found enlarged, with thin walls adherent to the duodenum and gastrohepatic omentum; pancreas was enlarged and hard; no duct stones palpable. It seemed to be an ideal case for cholecystoduodenostomy, as I wasn't positive of the pathology and yet there was need of biliary drainage. The after results were excellent; nausea and vomiting were present for a week in a moderate degree, but gradually the stomach irritation subsided; food was taken with relish and digested. In two weeks the jaundice was noticeably clearing up. Mrs. S. left the hospital a little over a month from her admittance. I have seen her several times during the intervening period (thirty-two months) but not professionally except once. She has never been better physically and is truly a happy and well satisfied expatient. The end results were good and in marked contrast to the previous case.

COMMENT

Both patients were of the same type. Both were past middle life, and presented a steady loss of weight and strength; both had enlarged liver and pancreas. Out of a clear sky appeared the jaundice; the slowly progressive jaundice without pain, so suggestive of malignancy. Sir Berkeley Moynihan says "Pancreatitis mimics both carcinoma and calculous forms of common duct obstruction, and no one living is infallible in the differential diagnosis. Therefore, operate as a guess is a poor peg upon which to hang a man's life!" Some short circuiting operation seems to be the method of choice. Its indications are, first, when the gallbladder is of any size and free, it is easy and can be done with little manipulation; second, when there is any doubt or question of pathology, as so often happens; third, when one cannot easily remove the duct stone; fourth, when one is dealing with malignancy, whether of the pancreas or of the liver, this procedure is the way out of the difficulty with ease and apparent safety. Of course such an operation cannot be done when the gallbladder is atrophied or when it is gangrenous or malignant, or the cystic duct obstructed.

All these obstructive jaundice cases need drainage over a long time, if not indefinitely, and how much happier the patient is, if the wound is neatly healed with no dirty, uncomfortable sinus, conveying bile to the outside, but in its place, there remains biliary drainage on the inside, going on continuously, bathing and healing any duodenal ulcerations that may exist. And if malignancy is present, the man is certainly far happier in his last days, and the bile salts are not lost to the body.

In considering these cases of icterus, quite recently DeTakats has taught us some helpful facts. Icterus is of two kinds; first, the complete icterus, which he calls cholemia, a condition where all the constituents of the bile are circulating in the blood stream (the pigment the bile acids and cholesterin). This is a serious condition and means a diseased and impaired liver function with its bad prognosis. The second kind of icterus is the partial type or bilirubinaemia, a condition where only bilirubin circulates in the blood. This is a harmless pigment and indicates a far more favorable prognosis. Blood analysis for the bilirubin index is therefore of great diagnostic help. It appears in the blood long before it is visible either in the tissues or in the urine, and so may help explain certain colics of unknown origin. While in all jaundice cases due to bile tract disease, if we know whether we are dealing with a cholemia or a bilirubinemia, we can be guided not only in our preoperative preparation but in our choice of anesthetics, and in our operative procedures. De Takats also stresses the application of Duke's test for the surgeon, because if the bleeding time is normal (two to two and one half minutes) we need not consider the coagulation time, as every toxic agent that prolongs coagulation time also effects bleeding time.

TREATMENT

The present accepted treatment in preoperative preparation for these cases is, first, intravenous solution of calcium chloride (three injections of five c.c. of a ten per cent. solution in redistilled water). Second, glucose intravenously and by hypodermoclysis; third, blood transfusion, and fourth, postponement of operation when jaundice is increasing, or bleeding time increased.

The postoperative treatment which is so important, I wish only to mention. Glucose is the most useful drug in all cases of liver incompetency; it supplies the liver with its needed glycogen, it combats acidosis, and is the very best nutrition for the heart. I use it in nutritive retaining enemas with soda, repeating every four or six hours. Proctolysis I have practically given up, partly because I believe that but a very small percentage of the solution ever reaches the circulatory system, and partly because the patient almost invariably objects after a few hours. Glucose, too, should be the drug for hypodermoclysis instead of saline and also for intravenous infusion.

Just recently there has appeared a method of satisfactorily giving a continuous intravenous drip, where an electrical coil with a connecting thermostat allows us to keep the solution both in the container and in the tubing at a regulated temperature. This seems most practical.

Hot packs over the liver, to help maintain internal respiration as suggested by Crile, should not be forgotten. Gastric lavage carried out early and often repeated is a necessity. A mistake very apt to be made is to postpone this treatment for too long a period, merely out of sympathy for the patient.

SUMMARY

1. Routinely consider the gallbladder and make an earlier diagnosis of cholecystitis, before the damaged tissue has become extensive and the patient has had months of impaired health, for the gallbladder is a site of infectious focalization far more often than we have realized.

2. Hepatitis and pancreatitis exist in most cases of chronic cholecystitis as an accompanying infection. They may clear up after a cholecystectomy or cholecystostomy but they may persist and cause intermittent biliary colic, post operatively, instead of a common duct stone, as is usually diagnosed.

3. Coronary thrombosis may assimilate a bile tract infection or exist in conjunction with it.

4. Blood analysis for the bilirubin index and the constituents of the bile is of great help in making early diagnosis—as well as in determining the operative procedure and prognosis.

5. The preoperative preparation of patients with obstructive jaundice, chiefly by blood transfusion, by calcium chloride solution intravenously, and by delay in operation until blood chemistry and venous bleeding time show an improvement is of great importance toward a successful operation.

6. Approach the operative procedure with a free mind and in applying treatment always consider the primary course.

7. There are many advantages in the operation of cholecystoenterostomy, if it be possible of performance.

8. The reestablishment of biliary flow very shortly after operation must be secured; otherwise tissue oozing, toxic nephritis with death will follow.

9. Use of insulin may tide us over a critical period and help establish the patient's carbohydrate tolerance, especially in the presence of pancreatitis.

10. Glucose is one of the most useful drugs in all cases with liver incompetency.

A complete bibliography will appear in the author's reprints.

The Value of Blood Transfusion in Subacute and Chronic Infections*

MARTIN LEWIS JANES, M.D.
New York

The more we delve into the speculations and thoughts of ancient man, the more strikingly are we forced to the conclusion, that basic conceptions and ideas regarding natural phenomena are as old as the power of reason and observation itself. The imagination of the ancients was fired by the conviction that the blood was essential for the life and well-being of all forms of animals, and consequently they attributed to it spiritual qualities. Thus, we find that in the crude ancient civilizations of Egypt, the value of blood transfusion as a therapeutic measure was known, and records show that it was practised.

Viewed in the light of the present day development of microscopy and our knowledge of hematology and seroimmunology we know that their vague thoughts regarding the value of blood transfusion as a therapeutic agent were not ill conceived. As we trace the alternating popularity and stormy vicissitudes which the procedure of blood transfusion experiences, from the first recorded blood transfusion at the end of the fifteenth century to a comparatively recent time, we cannot help but admire the indomitable will and unfailing courage of medical thinkers of the past, who had not only mechanical difficulties to overcome in transplanting the blood from donor to recipient, but also frequently encountered mysterious dangers, little understood, which sometimes caused posttransfusion reactions that were fatal.

MODERN METHODS OF BLOOD TRANSFUSION

That the transfusion of whole, unmodified blood is superior in value to blood adulterated by an anticoagulant is a matter of common knowledge which was established by the investigations of Novy and De Kruif (1), Drinker and Brittingham (2) and Clowes (3). The latter has pointed out, in a series of experiments, the similarity between sodium citrate and sodium chloride as to their general toxic effect upon protoplasm. The late Dr. Edward Lindeman, in a report of 214 transfusions without a chill, accounted for that remarkable result by his use of pure unmodified blood, introducing no foreign material, not even physiological salt solution, into the blood of his patients.

The syringe method, without any doubt, is the greatest advance that has thus far been made in surmounting the mechanical difficulties encountered in transplanting blood. It was with a desire to simplify the transplantation of blood so that with comparatively little skill it could be universally employed by the average physician, and in order also to eliminate the use of saline or other foreign material, that I began about six years ago, to experiment with various valves and combinations of syringes that would fill that requirement. An apparatus was perfected which was presented before the surgical section of the New York Academy of Medicine in 1920 and a description of which has been published (4). The apparatus provides an uninterrupted flow of blood from donor to recipient, requires only one man to operate it, and reduces the length of time necessary for a transfusion, two syringes being in action instead of one. No saline solution is necessary to prevent clotting, as there is no stagnation of blood during the course of the operation, the flow of blood from donor to recipient being practically continuous. The apparatus, being a one man affair, enables one to use it in his office or patient's home without any assistant and with comparative ease.

BLOOD TRANSFUSION IN INFLUENZA PNEUMONIA

That blood transfusion in frequently repeated doses of five hundred c.c. every twelve to twenty-four hours, from actively or passively immunized donors is of value in desperate pneumonias complicating influenza is brought out in a report by Ross and Hund (5). In these advanced cases they found the coagulability of the blood markedly diminished, and by the introduction of normal blood platelets by means of blood transfusions, the coagulating power of the blood was restored to normal.

Using patients recently convalescing from pneumonia, that is, those convalescing from two days to six weeks from pneumonia, when the immune content of their blood is at its height, they report the following remarkable results from frequently re-

*From the Surgical Service of Dr. Charles Gordon Heyd, New York Postgraduate Medical School and Hospital. Read before the Bronx County Medical Society, October 15, 1924.

peated blood transfusions: "A definite localization of the pneumonic process with progressively increasing leucocytosis and resolution, rapid clearing of the cerebrospinal, respiratory, cardiovascular and renal disturbances, diminished acidosis and normal temperature for from twenty-four to seventy-six hours following the transfusion."

From a study of a series of fifteen cases, three of which I shall cite below, I am forced to the conclusion that blood transfusion has a remarkably beneficial effect upon a patient generally and upon a suppurating wound locally. Its action may be explained as follows: First, its stimulating effect upon the hematopoietic system: the transplantation into the circulation of healthy red blood cells and compliment, causes a stimulation of the function of the opsonins and the phagocytic power of the white blood cells, thus materially awakening the dormant powers of the patient to combat the infection. Second, its effect in overcoming various grades of anemia dependent upon subacute or chronic sepsis. Third, the effect of blood transfusion in staying or counteracting various degrees of emaciation and partial marasmus and in increasing the resisting powers, physical, chemical and immunological, of the patient. That blood transfusion saved at least one patient's life is quite apparent from the following observations:

Case I.—Patient, H. B., male, aged fifty-three, foreman, admitted to the service of Dr. Charles Gordon Heyd, at the New York Postgraduate Medical School and Hospital, April 9, 1924. The family and previous histories were irrelevant.

While working in a factory, he bumped his left elbow against a machine. Four days afterward there developed what appeared to be a boil, which gradually grew in size and extent until his entire left arm and forearm became markedly swollen, red and inflamed.

Examination upon admission revealed an infected left olecranon bursa and cellulitis of the left arm and forearm. His temperature on admission was 104, pulse 128, respiration 28. His blood count was 10,000, eighty-six per cent. polymorphonuclears, ten per cent. small lymphocytes, one large lymphocyte, one eosinophile and two transitionals.

Four days after admission there developed a diffuse cellulitis of the left arm, forearm and hand and streptococcus hemolyticus was isolated from the wound. He was then operated upon, multiple incisions being made and suitable drainage established.

On April 26th, streptococcus hemolyticus was isolated from the blood. His temperature and pulse since admission ranged between 100° and 105° and 100 and 130, respectively. On May 7th he was given a transfusion of 500 c.c. of whole blood. His blood count on May 9th was 22,000, polymorphonuclears eighty per cent., lymphocytes thirteen per cent., transitionals five per cent., mononuclear leucocytes one, basophiles one.

Following the transfusion, there was a remarkable improvement in the patient's general condition and quite an apparent improvement in the wound, with a gradual recession of the temperature. Four days after the transfusion the temperature and pulse were 99° and 104° respectively. Thereafter until his discharge the temperature ranged between 99° and 100° and the pulse between 90 and 110. On May 24th, he was discharged convalescing and the wound healing.

Case II.—D. A., male, aged two and one half, years, admitted to the Post-Graduate Hospital September 11, 1923. The family and previous histories were irrelevant.

Two months prior to admission there developed in the patient an abscess of the neck which was opened by the family physician. Three weeks later the patient began to suffer from a cough and fever, the family physician, making a diagnosis of pneumonia, advised admission to the Postgraduate Hospital.

Upon admission the patient had a temperature of 98.6°, pulse 162 and respirations 46. Physical examination revealed all the cardinal signs and symptoms of the following conditions: 1. Pleural effusion, right side, 2, bronchopneumonia, 3, pneumothorax due to thoracentesis, and, 4, diseased tonsils and adenoids.

He showed all the signs and symptoms of a toxemia and bacteremia, with an apparently poor response to the infection.

His temperature from the day of his admission to September 22nd ranged between 99° and 102°, pulse 100 to 160 and respirations 30 to 48. On that day he was given a transfusion of 80 c.c. of whole blood. On the following day his temperature, pulse and respiration fluctuated between 99° and 100°, 100 and 120 and 26 to 36 respectively, until September 29th, when a resection of a rib was performed, which caused his temperature to rise to 103.5°, pulse 160 and respirations 60. Thereafter the condition ran a characteristically septic course, the temperature, pulse and respiration fluctuating daily between 99° and 104°, 130 to 164 and 36 to 50 respectively. On October 13th, another transfusion of one hundred c.c. of whole blood was given. Following the transfusion the temperature gradually receded. On October 21st, his temperature reached 99°, pulse 136 and respirations 22, with a marked improvement in his general condition. Thereafter his recovery was progressive and uneventful and he was discharged convalescing, November 7, 1923.

Case III.—L. H., female, aged twenty-three, housewife, married one year. The family and previous histories were irrelevant.

Two weeks prior to my being called upon to give her a transfusion, she was delivered of a normal, mature nine pound boy. Seventy-two hours afterward a slight fever developed, and she complained of headache, general malais and pain in the back. At about the same time her attending obstetrician noticed a foul smelling, purulent, vaginal discharge, which resisted the usual forms of treatment. Since then she had a typically septic temperature, pulse and respiration which fluctuated daily between 100° and 104°, 110 to 130 and 24 to 30 respectively.

Her blood picture just prior to transfusion was as follows: Red blood cells 3,100,000, hemoglobin by Sahli method 52 per cent., white blood cells 18,000, polymorphonuclears eighty-two per cent., small

lymphocytes fourteen per cent., large lymphocytes three per cent., and eosinophiles one per cent.

I gave her a transfusion of one thousand c.c., the husband acting as donor. Twenty-four hours after the transfusion her temperature dropped to 100°, pulse 106 and respirations 26. There was an apparent and striking improvement in the general condition of the patient, who became cheerful, took a greater interest in her environment and asked for nourishment. The vaginal discharge was diminished in quantity and altered in quality. Forty-eight hours after the transfusion, her temperature was 99°, pulse 100 and respirations 26. Her blood picture was as follows: Red blood cells 4,100,000, hemoglobin seventy-six per cent., white blood cells 14,600, polymorphonuclears seventy-six per cent., small lymphocytes sixteen per cent., large lymphocytes six per cent., eosinophiles one per cent., and basophiles one per cent.

The patient thereafter continued progressively to improve and made an uneventful recovery.

CONCLUSIONS

1. Whole blood, because of its nutritive and bactericidal properties, is an unexcelled stimulant.
2. Blood transfusion is of unquestionable value in combating infection, toxemia and bacteremia and in overcoming anemia. It should not be used as a last resort but as a therapeutic procedure.
3. No patient whose response to infection is below normal should be allowed to struggle on against that infection without the stimulation of a blood transfusion.

Report of a Method of Resuscitation in Asphyxia Neonatorum

SIMON REISLER, M.D.
Indianapolis, Ind.

A method of resuscitation of the newborn consisting in the insufflation of the vapors of aromatic spirits of ammonia, was first improvised and used successfully by me in a case of asphyxia pallida neonatorum, which resisted all efforts at resuscitation by the standard methods. This case occurred in my practice on July 4, 1923, and is the only one in which I had occasion to give the method a fair trial. I have since communicated the method to other physicians who have reported successful results in all cases in which it was tried, including only such cases in which resuscitation by other means failed. Beside the original case, five cases are reported by Dr. Lawrence Gilman from the service of the Indianapolis City Hospital, one case by Dr. L. H. Stafford, St. Francis Hospital, and one case by Dr. W. F. Johnson, Methodist Hospital. Dr. Johnson also used the method successfully in three additional cases of lesser severity, which are not reported. The total report of eight cases, though representing a comparatively limited experience, is at the same time remarkable for the strikingly uniform results obtained in such severe cases, as well as for the absence of failures. It is to be noted that in five of the eight cases reported mouth to mouth insufflation without ammonia was first tried as a control, without success.

METHOD

On a piece of gauze wrung out of warm water, put three or four drops of aromatic spirits of ammonia, the gauze placed over the mouth of infant, mouth to mouth insufflation is practised at the rate of about thirty a minute, being careful not to overdistend the infant's lungs, and assisting expiration by slight pressure over the chest. More ammonia is added as insufflation proceeds, using three or four drops at a time only.

In looking over the literature for the past fifteen years, no mention could be found of the use of ammonia by insufflation in the treatment of asphyxia neonatorum. The only references to the use of ammonia in the treatment of asphyxia of the newborn were found in a series of articles in the New York Medical Journal for 1909, in answer to the prize question: How Do You Treat Asphyxia Neonatorum? Dr. Sara E. Foulks (1) wrote: "A few drops of aromatic spirits of ammonia upon a piece of absorbent cotton may irritate the nasal mucous membrane to such an extent that respiration not only begins, but movements of the whole body are reflexly instituted." Dr. C. L. Sigler (2) said: "If there is any effort at all at respiration, inhalation of stimulants as aromatic spirits of ammonia or camphor may be tried." Dr. Joseph Baum (3) wrote: "In extreme cases the inhalation of strong ammonia and the hypodermic injection of strychnine sulphate one one hundred and fiftieth grain are of great use."

As is well known, the empirical use of aromatic spirits of ammonia as a heart and respiratory stimulant in emergencies is quite general, but there is still some dispute as to the mode of action of inhaled ammonia vapors. Poulsson (4) states: Inhalation of dilute ammonia produces by reflex from the nasal mucous membrane to the medulla, vasoconstriction and heightened blood pressure, cessation of respiratory movements for a moment, and then deeper respiration. Cushny (5) quotes: The epithelium of the lungs has been stated to be impermeable to the ammonium ion, but this appears to be incorrect. (McQuigan) (6). In discussing the action of inhaled ammonia, Cushny further states: When inhaled, the irritation of the mucous membrane causes a reflex stimulation of the vasomotor centre, and consequent contraction of the arterioles

and augmented blood pressure, while the respiration is first arrested, and then becomes deeper and fuller. The heart may be temporarily slowed by inhibitory reflexes. Hare (7) states: The injection of ammonia in moderate quantities into the blood, causes an acceleration of the rate of respiration due to stimulation of the respiratory centre, the respiratory movements becoming not only more full, but also more rapid. If the drug is inhaled in small amounts or swallowed, the same action is seen in a less degree, the changes both in breathing and in circulation being partly due under such circumstances to a reflex irritation transmitted along the sensory nerves.

My conception of the therapeutic effects obtained from insufflation of the vapors of aromatic spirits of ammonia in asphyxia neonatorum is as follows: The collapsed lungs are distended, the alveolar capillaries fill up, thus reducing the pressure in the right heart and helping in the closure of the foramen ovale. The insufflated ammonia vapors stimulate the mechanism which normally initiates respiration, the establishment of which is naturally and to a great extent dependent on reflex stimulation of the cord and vasomotor centre from the body surfaces. Reflex stimulation of the cord initiates contraction of the muscles of respiration, reflex stimulation of the vasomotor centre promotes a proper distribution of blood to the vital centres in the medulla as well as to the body in general. It is evident that the vasomotor centre is the main focus of disturbance in asphyxia neonatorum, since both forms of asphyxia, namely, pallida and livida, represent phenomena referable to vasomotor function. In addition to this reflex effect, some ammonia at least penetrates the alveolar epithelium and produces the direct stimulating effects characteristic of injection of ammonia into the blood. The method is ideal because it combines the effects of physical distention of the lungs, reflex on medulla and cord, action of respired air containing an excess of carbon dioxide, and the stimulating ammonia vapors.

Case I.—Infant C. B. S., weight nine pounds, born at home, July 4, 1923, 5 a. m.; normal labor lasting five hours. Maternal medication; morphine sulphate one sixth gr. hypodermically about three hours before delivery; pituitrin one half c.c. fifteen minutes before delivery. Position L.O.A., cord normal. No signs of respiration or cry; pallor, relaxed state. Heart beats feeble, about 140 a minute. Resuscitation began by clearing the mouth and throat, holding infant by the legs, slapping its back and using cold spray. When it was apparent that no results would follow, the cord was cut and tied, artificial respiration performed by Sylvester method, and heat applied. A few minutes of this without the slightest results, and mouth to mouth insufflation was tried for several minutes with no result. By this time, the heart beats had slowed down to the alarming rate of thirty a minute. The next thing tried was an injection of three drops of aromatic spirits of ammonia, when the feasibility of insufflating ammonia vapors presented itself. On a piece of gauze wrung out of warm water were put two drops of aromatic spirits of ammonia, the gauze placed next to the mouth of the infant, and mouth to mouth insufflation was practised at the rate of about thirty a minute, care being taken not to overdistend the infant's lungs. Expiration was assisted by slight pressure over the chest. After about six insufflations the infant produced a spontaneous respiration. Insufflation was practised a few more times, and shortly normal respiration was established. No ill effects followed and the infant was healthy when seen last, two weeks later.

The following five cases are reported by Dr. Lawrence Gilman from the Indianapolis City Hospital:

Case II.—Patient H. W., primipara, admitted 4.50 p. m., March 15, 1924. In labor thirty-six hours, forceps delivery, ether anesthetic. Infant born 8.50 p. m., pallid, refused to breathe spontaneously. The following methods of resuscitation were attempted in the order given: spanking, dipping in cold and warm water alternately, irritation of soles of feet, warm bath, artificial respiration, mouth to mouth insufflation, with no results. Then insufflation of aromatic spirits of ammonia was instituted. Three to four drops of the ammonia spirits were placed on a moist square of gauze, interposed between mouth of infant and accoucheur, and mouth to mouth insufflation carried on. The child breathed after a short period of insufflation (ten to twenty seconds) and continued. Breathing began gradually and without gasping. Infant gained weight normally and left the hospital with its mother, March 24, 1924.

Case III.—Patient, N. B., primipara, admitted 1 p. m. February 4, 1924, breech presentation. Twilight sleep and ether. Labor lasted twenty-eight hours. Delivered of female child at 7.40 a. m. February 5, 1924. Infant blue; did not breathe spontaneously from 7.40 a. m. to 8.15 a. m. The following methods of resuscitation were tried: spanking, irritation of soles of feet, hot bath, artificial respiration, dipping in warm and cold water alternately, folding, mouth to mouth insufflation, all failed. At 8.15 a. m. three or four drops of aromatic spirits of ammonia were placed on gauze over the patient's mouth, and mouth to mouth insufflation instituted. After about fifteen seconds of insufflation of the fumes, the child cried and began automatic respiration. The child continued to breathe until about midnight when last observed, but was found dead in its crib at 12.30 a. m. by the nurse. No autopsy was allowed.

Case IV.—Patient B. H., primipara, admitted 7.30 a. m. March 8, 1924, twilight sleep. Delivered of nine pound male infant, March 8, 1924, 2 p. m. Infant blue and refused to breathe after the usual means of resuscitation were employed, including mouth to mouth insufflation. Then insufflation of aromatic spirits of ammonia was resorted to and infant breathed in less than twenty seconds after the institution of the above procedure and continued. Left hospital March 17, 1924, with mother.

Case V.—Patient M. B., primipara, admitted 11.50 p. m., March 10, 1924. Delivered of eight pound infant at 7.10 p. m., March 11, 1924. Infant pallid, refused to breathe. Usual means of resuscitation failed. Infant resuscitated by insufflation of aromatic spirits of ammonia. Child was normal, lost one pound six ounces in weight, but gained back fifteen ounces before discharge with mother, March 21, 1924.

Case VI.—Patient F. B., primipara, admitted 3 a. m., March 15, 1924. In labor forty-eight hours.

Infant pallid, did not breathe. Resuscitation by insufflation of aromatic spirits of ammonia after the usual methods of resuscitation failed. Child was normal and left hospital with mother, March 24, 1924.

Dr. L. H. Stafford's case, St. Francis Hospital:

Case VII.—Patient M. M., primipara. Admitted August 19, 1923. Patient in labor twelve hours. Caesarean section done, August 20th, 1.40 p. m. Infant pallid, refused to breathe. Usual methods of resuscitation including heat, artificial respiration failed. Infant responded immediately after insufflation of aromatic spirits of ammonia was instituted. Patient in good condition, discharged August 30, 1923.

Dr. W. F. Johnson's case, Methodist Hospital.

Case VIII.—Patient M. N., boy, ten pounds, born July 14, 1924. Ether anesthetic. Labor lasted twelve hours. Bones of head firm and fontanelles small. After delivery of head, it was fifteen minutes before shoulders could be delivered, giving the placenta time to dislodge. After delivery, cord was white with no pulsation. Infant pallid and apparently dead. Unable to get any sign of heart beat or breathing, no eye reaction. The usual methods of resuscitation were tried, including artificial respiration, application of heat and mouth to mouth insufflation with no results. The infant seemed dead and the interne and head nurse also thought it was dead. Then insufflation of ammonia was tried. Three drops of aromatic spirits of ammonia were placed on a cloth and blown into the child's mouth, getting a slight quiver. More ammonia was added about every minute, forcing respiration regularly. In about ten minutes there were signs of heart action but no natural breathing. Insufflation of ammonia was continued for about a half hour before the infant would breathe of its own accord. Then oxygen was used for about six hours. The baby lives and is growing finely. No ill effects followed the prolonged insufflation of ammonia. The infant was kept in the incubator for twenty-four hours.

CONCLUSIONS

The method could be modified so that in hospitals, where special apparatus is available, the ammonia vapors may be insufflated with their aid. In severe cases, it is advisable to inject two to five minims of aromatic spirits of ammonia hypodermically, in addition to insufflation, in order to gain continuous stimulation. Care should be taken in not using too much ammonia at one time, for a too high concentration of the vapors may produce bronchitis or pneumonia (8). This may be avoided by using only three or four drops at a time. The last case reported emphasizes the possibility of resuscitating apparently dead infants whose circulation is practically at a standstill. The important factor is that reflex action may still be elicited when all other vital phenomena have apparently disappeared and in such cases of suspended animation, effective stimulation may be obtained by the above means.

The Surgical Treatment of Abscess of the Lung*

HENRY F. GRAHAM, M.D., F.A.C.S.
Brooklyn, N. Y.

We assume that the patient has received all the possible aids to diagnosis and that the area of pulmonary suppuration has been located as accurately as possible by means of stereoscopic x ray films, the bronchoscope, if necessary, and a careful physical examination. If a foreign body was the exciting cause it has been removed, if possible, by the use of bronchoscopic forceps. Postural drainage, fresh air, and forced feeding have all been employed, but at last we are forced to the conclusion that more radical measures must be used.

What further resources have we to summon to our aid?

1. Bronchoscopic treatment: dilatation of a strictured bronchus or lavage; 2, pneumothorax; 3, drainage of the abscess from the exterior; 4, extrapleural thoracoplasty, and, 5, lobectomy by either the original methods or, preferably, by the actual cautery destruction. Before discussing these in detail we must briefly consider a few important facts.

It is of the utmost value to determine: 1. Is the abscess single and well encapsulated? 2. Is there a diffuse area of pulmonary involvement with multiple abscess points like a honeycomb occupying a considerable portion of a lobe? 3. Is it chiefly a bronchiectatic dilatation? 4. Is it centrally located, or, is it peripheral? 5. Are pleural adhesions present?

Let us now take up the methods of treatment at greater length. Bronchoscopic treatment has been used in a number of cases. The late Dr. Lynah was one of the pioneers in this work. No one can question its value for the removal of foreign bodies or to make drainage more free in centrally located abscesses, or to determine whether the pus comes from the middle or lower lobe.

On theoretical grounds I am inclined to agree with Chevalier Jackson when he says: "In no case of lung abscess whatever should bronchoscopy be used for

*Read before the Brooklyn Society of Internal Medicine, October 24, 1924. Part of a Symposium on Lung Abscess.

treatment and thoracotomy delayed." Further experience may alter this dictum.

Lambert and Miller say "Bronchoscopic lavage, which was used in only three cases, gave indifferent results." I, myself, have seen one or two failures of this kind.

Pneumothorax is indicated only in central abscess when operation would be dangerous or impossible. Essential requirements for this are the absence of pleural adhesions and the presence of free bronchial drainage. Tewksbury has reported fourteen cases thus treated with eleven cures and two deaths. Lambert and Miller say "It was used very little. In peripheral abscesses its use is dangerous because of the risk of rupture of the lung and secondary pyopneumothorax . . ." Hedblom says "The results are disappointing. Cases must be recent ones. The trouble is that in most cases adhesions or the condition of the lung itself prevents collapse."

Drainage of the abscess would seem to be the simplest and most logical method of treatment, but once again, "There is a fly in the ointment." The solitary, walled off abscess is rare. It is much more common to find general bronchiectatic dilatation with an area of involved lung surrounding it, or multiple miliary abscesses scattered throughout a lung area. For such conditions simple tubular drainage is futile. The posttonsillectomy abscess is often of this bronchiectatic type.

Extrapleural thoracoplasty is used in multiple bronchiectasis. It consists in an extirpation of the bony thoracic wall overlying the involved area of lung. Hedblom says of this operation, "There are many bad results, probably due to failure to perform an extensive enough operation, or to too extensive an operation at one sitting. To a greater or less degree this operation must form the basis of any radical work performed for the cure of lung abscess."

Lobectomy is a radical attempt to remove the affected tissue as in an appendectomy or cholecystectomy. By the original methods, formerly in use, this gave a mortality of fifty per cent. in a combined series of sixty-two cases.

Evarts Graham, professor of surgery in Washington University, St. Louis, has recently (1923) advocated partial pneumectomy with the actual cautery—a soldering iron heated to a cherry red heat. His original communication reported three cases without a death. Other cases have since been reported. We will describe his method in greater detail later on.

OPERATIVE TECHNIC

The operation is preferably delayed until the acute stage has subsided. A one stage operation is done only in those desperately ill, with high temperature and sepsis. The patient empties his lungs by the inverted position immediately before operation. As a number of successive steps must be taken it is important that the first operation should be painless. Local anesthesia with the aid of a little gas-oxygen is used. A posterior paravertebral incision at the angle of the ribs makes it possible to inject the intercostal nerves with novocaine and alcohol and thus render the chest wall insensitive for future procedures.

A portion of the ribs six to ten cm. long is resected and the wound closed. Later the anterior end of the same ribs is removed. This may be enough, but, if necessary, other steps remove the central portions. If thoracoplastic collapse is the aim in view it can now be secured.

If cautery excision of an affected lobe is desired less extensive exposure will suffice. Adhesion of the lung to the chest wall is absolutely necessary. Usually it is present, but, if it is absent, it must be induced.

The diseased portion of the lung is then directly attacked by the red hot soldering iron and an excavation made in the lung tissue. The operation is really a lobectomy done with the actual cautery. It may be divided into as many stages as are desired or considered necessary. At its completion a large cavity is left with a charred lining. This separates in two weeks. Secondary hemorrhage would, theoretically, be feared, but has not occurred in the reported cases. If it should occur, packing would easily control it because of the low pressure in the pulmonary artery.

AFTERCARE

This consists of fresh air, forced feeding, postural drainage, if indicated, and especially of heliotherapy and exposure of the wound to the air.

Although no extensive series of cases has yet been reported of operations by this method, the results seem to be far better than by any other method and it seems to open up a new avenue of hope to these miserable sufferers. Dr. Graham has reported seventeen cases with only one death.

STATISTICS

Whittemore says that "from ten per cent. to thirty per cent. of the cases may be expected to be cured by expectant treatment. Artificial pneumothorax may cure a small number. Bronchoscopic treatment may cure a limited number if treatment is established early. Surgery offers an excellent chance for cure in those cases in which other methods of treatment have failed or are unsuitable." His mortality in one hundred cases was eighteen. He says: "Sixty per cent. to seventy per cent. may be cured or permanently improved. About five per cent. do well at first but later develop hemorrhages and a recurrence of sputum and die."

The Mayo clinic in its 1923 volume reports on forty-six patients with chronic abscess; twenty-two were completely cured; twelve were improved; one was not improved; and nine died, a mortality of about twenty per cent. There were thirteen cases of bronchiectasis subjected to a graded thoracoplasty without a death. All were improved and five were nearly cured. Three were recent cases and the end result was not yet known. Five patients had an abscess combined with bronchiectasis and received a graded thoracoplastic collapse. Three of these died and two were cured, but one of them is a social recluse because of foul breath.

In those who died an autopsy revealed multiple abscesses and bronchiectasis in all.

The history of this condition shows a dark and dismal past, a brighter present and indications of the dawning of a more brilliant future.

Enuresis*

SAMUEL A. MOSS, M.D.
New York

Enuresis usually is first noticed as a distressing and abnormal condition in the fourth or fifth year; it may extend to puberty and may continue throughout adult life. There is no distinct age line of demarcation between the physiological and pathological condition in young children, but the trained child usually controls his bladder at the age of four, and some children even at the age of three or two. Enuresis is not noticed as a rule until the child reaches the fourth or fifth year. He then begins to wet himself quite regularly one, two or three times a night. It is usually nocturnal and occasionally is both diurnal and nocturnal. Both sexes are affected with equal frequency. In most cases the condition will cease spontaneously about the eighth year, but sometimes persists until puberty and relatively rarely it may continue to full maturity.

Since the vascular and nervous supplies of the bladder and sexual organs are closely related, it is probable that the development of the latter may have some influence on the urinary apparatus, and in this way might be responsible for the disturbance in the function of micturition.

Before going into the etiology and pathology of enuresis it might be well to take up very briefly the physiological processes involved in normal micturition. Two centres are recognized which control the urinary function. One, situated in the lumbar and sacral regions of the spinal cord, known as the tonus centre, maintains the tonic contraction of sphincters. This centre is bilateral and each half controls the entire bladder (1). The second and higher centre, situated in the cerebrum, designated the inhibitory centre, controls the lower or tonus centre. Grünbaum and Sherrington (2), in their experimental work on apes, place the cortical centres for the rectal, bladder, and sexual functions at the apex of the motor convolution, in other words, in the foot centre. Czylharz and Marburg place the cortical centre of the bladder in the hip region. It is evident that a cerebral condition must be bilateral to cause total paralysis of the urinary function. Urination is therefore not so much a direct voluntary action as an indirect action of the brain in removing or relaxing its control on the spinal centre. It is well also to remember that the sphincters are always under tonic contraction and that the bladder empties itself by the voluntary relaxation of the sphincters and contraction of the detrusor muscle.

In children it has been found that the detrusor muscle is much thicker and stronger than in adults, and the sphincters correspondingly weaker. Chetwood (3) thinks a possible explanation of enuresis may be found in the fact that there is a disparity between the detrusor and sphincter muscles, the action of the former being much stronger than that of the latter; and when the exercise of the will is lost, during sleep, the urine is forced involuntarily from the bladder. Again, the direct desire for micturition is produced by a sense of fullness in the bladder which is directly due to an increased amount of tension or pressure in that organ. This increased pressure causes sensory stimuli to be transmitted to the higher centre which in turn removes its inhibitory control on the lower centre and reflexly brings about contraction of the bladder wall. Another direct factor in the function of micturition is the voluntary relaxation of the sphincters, and still another is the contraction of the bladder wall. It has been shown recently by Amberg (4) that there is no real sphincter in the anatomical sense, but that there is a functional sphincter, which is made up of the longitudinal and circular fibres of the bladder wall.

From the viewpoint of normal physiology of micturition, therefore, we can classify the abnormal condition of enuresis as follows: first, pathological increase in the output of urine thereby producing increase in tension. This occurs in diabetes mellitus, diabetes insipidus, lithiasis, phosphaturia, cerebral conditions; second, reflex origin; the bladder wall is extremely sensitive to reflex stimulation and every psychical act and every sensory stimulus is likely to cause contraction of the bladder muscle. In this class are included all conditions which are capable of producing reflex contractions of the bladder wall, namely, phimosis, paraphimosis, epispadias, hypospadias, balanitis, adherent clitoris or penis, pin worms, adenoids and tonsils, renal or vesical calculi, pyelitis, masturbation, vaginitis, skin diseases of the genital organs, tuberculosis of the genitourinary tract. We may also include in this class all neurotic and psychic conditions which produce reflex contractions of the bladder wall. It occurs quite often in children with neuropathic tendencies. In these cases enuresis either precedes the neurosis or aids in its production. It is usually accompanied by ideas in dreams which are referable to micturition. A third class includes idiopathic or functional disturbances, in which the most careful examination does not reveal any noticeable or specific cause; fourth, the class of cases resulting from endocrine disturbance.

In the first and second classes the successful outcome of treatment depends upon the thoroughness of the examination; the treatment will be simplified if the cause can be discovered and treatment directed thereto. Thorough search for the focal point of irritation must be made. Careful examination of the urine for albumin, sugar, pus, and bacteria is absolutely necessary. The anus and rectum should be examined for fissure, pin worms, prolapse and eczema. If the clitoris or penis is adherent, stripping and separation of the adhesions is required; in phimosis, circumcision is often curative; in a mouth breather, pathological adenoids and tonsils should receive attention; in masturbation, moral influence is requisite; in hyperacidity, alkaline medication combined with hyoscyamus and belladonna, plenty of water during the day, correction and regulation of

*From the Urological Department, Beth Israel Hospital, service of Dr. Abr. L. Wolbarst.

diet. Epilepsy must be excluded by having the child watched through several nights.

In those cases in which no specific cause can be determined, the following general instructions are given to the parents. Regulation of diet; all irritating articles of food especially tea and coffee should be avoided; improve hygienic conditions; fresh air, exercise and frequent bathing. Little or no fluids should be taken at least three to four hours before bedtime. Empty bladder immediately before retiring. The child must be awakened at a stated hour usually one or two hours after falling asleep and again during the night if that is found necessary. It will be found that the hour of bedwetting is usually fairly constant, and the child should be awakened to void about one half hour before its habitual time of involuntary micturition. In due time the child will acquire the habit of getting up of its own accord. Training the child to awaken voluntarily is the one essential towards a permanent cure. Scolding and punishing the child help little and often aggravate the condition.

Atropine and belladonna are the drugs usually employed. These drugs act on unstriped muscle fibre and the effects are probably due to allaying the excessive irritability of the muscular coat of the bladder. We have had excellent results at our clinic with tincture of belladonna, gradually increasing the dose, beginning with ten drops three times daily, until the physiological effect has been obtained; this is made manifest by dryness of the throat, flushing of the skin and loss of accommodation. Atropine sulphate may be used instead of belladonna, administering one grain to two ounces of water, so that one drop contains about one thousandth of a grain of the alkaloid and increasing the dose one drop every day until enuresis is controlled or toxic symptoms develop. Saxl and Kurzweil (5) have given as much as one twenty-fifth of a grain of atropine sulplate without untoward effects. F. DeAngelis (6) and Carl Pototsky (7) have used camphor with success. They believe that the camphor has a sedative effect upon the genitourinary organs. Its effect, if any, may be due, first, to a depression on the inhibitory centre of the brain, later the spinal cord, and lastly on the terminal endings of the motor nerves. From experiments it would seem to interrupt the connection between the sensory and motor cells (8). DeAngelis (6) reports improvement or cure of enuresis in six of eleven cases by giving injections of camphor from one to six evenings. Carl Pototsky also has obtained excellent results by the employment of camphor. He prefers a combination of pure camphor and bile acids known as codechol. He gives four codechol tablets daily for a period of two weeks and repeats the treatment if necessary after an interval of a few weeks.

Amberg (4) mentions the experimental work of Weitz and Gotz who used a manometer to test the pressure changes in the bladder. They found that the bladder of enuretics behaves exactly like the bladder of normal persons in regard to pressure changes but that there was one significant difference, namely, the enuretics experienced no desire or little desire for urination. In order to increase the sensitiveness of the bladder they introduced silver nitrate solution from one to 4,000 to one to 750 into the bladder to its full capacity. They claimed good results in more than fifty per cent. of the cases.

Electricity has been extensively employed, the anode placed over the lumbar regions and the cathode over the bladder or on the perineum. The good results claimed by some are probably psychical. The same applies to the urethral electrode. Sounds and deep instillations of silver nitrate one half to two per cent. are useful in cases due to a hyperesthetic posterior urethra. Epidural and retrorectal injections from five to fifty c. c. of normal saline (9) have been used and its good effects are thought to be due to the stimulation of the inhibitory centre. Fluid extract rhus aromatica ten to eighty minims three times daily has been stated by some to have given remarkable results. Keersmacher claims excellent results with tuberculin. He believes that enuresis is a manifestation of slight general pulmonary tuberculosis (10).

Regarding endocrine disturbances: Sundell (11) believes that the predominating cause of enuresis is found in the dulling of the cerebral perception. He has had good results in children with the use of thyroid, especially in those cases with backward mentality. Hertoghe and Williams (12) also report good results with thyroid. They give children under six, one half grain twice daily and older children one to three grains twice daily. Saxl and Kurzweil note that many children with definite stigmata of hypothyroidism and pituitarism do not have good control over urination especially during sleep. In a series of thirty cases at the Beth Israel Clinic we have had striking results with pituitary substance, one grain three times daily and gradually increased, if necessary, to three grains three times daily. Many of these cases failed to reveal any specific cause or signs that might help in the diagnosis. Tincture of belladonna, atropine sulphate, quinine, and other drugs were employed, as well as mechanical means, such as deep instillations, sounds and electricity, all without results, until pituitary body was administered. In many cases improvement occurred almost immediately. In fifty per cent. of the cases, a definite cure was noted, twenty-five per cent. showed marked improvement after two weeks to three months. Whether the pituitary increases the inhibitory action of the higher centre on the lower centre or diminished the irritability of the lower centre so that it does not respond so readily to the various stimuli, or whether it increases the tone of the bladder muscle, has not been definitely determined as yet. This still requires much further investigation.

Practical Therapeutics

INTRAVENOUS THERAPY; A RETROSPECT

W. Forest Dutton, M.D.
Amarillo, Texas

The history of intravenous therapy dates from the seventeenth century. Although certain allusions to this form of treatment are made in the fragments of Egyptian history, authentic evidence is lacking. The *Wisdom Book of Tanaquila* refers to the custom which appears to be blood transfusion, and Howphile's *Treatise on Anatomy* clearly refers to it.

Many references are made in ancient, profane, and sacred literature to blood transfusion, but few report its success as a therapeutic measure.

The discovery of the circulation of the blood by William Harvey (1613) made possible the realization of that which previously had been a mere figment of imagination. Any attempts at blood transfusion before the time of Harvey's discovery were undoubtedly elusive fabrics of experimental endeavor because of two important facts: 1. That the idea of this operation could not occur to anyone to whom the circulation of the blood was unknown; 2, that the phenomenon of the circulation of the blood was not discovered until the seventeenth century.

Harvey's book, *De Motu Cordis,* was published, in 1628, at Frankfort. In 1652, Francisco Folli wrote a book on blood transfusion which gives evidence that he was familiar with the theory of transfusion, that he had worked out a technic for it, and invented instruments for carrying it out. The first authentic record is that published in the *Philosophical Transactions* for January, 1667, wherein Richard Lower gave a complete and detailed account of the technic of blood transfusion.

The possibility of administering medicine by direct admixture with the blood stream probably coexisted from the beginning with the idea of transfusion, but the first authoritative record of any such attempt is found in the *Transactions of the Royal Society* of England, volume 1, page 96, where Robert Boyle, the celebrated physicist and chemist, states that early in the year 1657 the suggestion of intravenous medication was made to him, not by a physician or a physiologist, but by an architect —no less a person than Sir Christopher Wrenn himself. The experiments undertaken at Sir Christopher's suggestion by Timothy Clark, Robert Boyle, and Nathaniel Henshawe were not crowned with startling success, and this further complicated the vexed question as to national precedence in the introduction of intravenous therapy.

The English, French, Germans, and Italians of this time were all participants in the controversy over priority.

Much experimentation was done the following one hundred years, and, notwithstanding the Cassandra like prophecies, little progress was made in intravenous therapy until after the discovery by Landois, in 1875, that animal serum will hemolyze human blood.

The subsequent discoveries of Maragliano (1892), Landsteiner (1901), and Eisenberg (1901), that the sera of diseased and even normal donors will hemolyze alien blood, have revolutionized the whole subject of transfusion and made intravenous therapy possible.

In 1903, I found, after three years of research, that iron cacodylate, sodium cacodylate, sodium cinnamate, sodium citrate, sodium iodide, sodium thiosulphate, solution of iodine compound, strontium bromide, diuretin, hexamethylenetetramine, collargol, calcium chloride, antimony and potassium tartrate, and quinine and urea hydrochlorate were applicable in disease by intravenous administration. This was well supported by clinical evidence.

The introduction of therapeutic agents into the circulation was uncommon. When this method was used the physician brooked the censure of his confrères and controversies were inevitable. The advent of Ehrlich's discovery, made public in 1910, marked the greatest innovation in intravenous therapy.

Ludwig Hektoen, of Westby, Wisconsin, first pointed out the possible danger from isoagglutination in the transfusion of blood. The work of Janksy (1907) and Moss (1910) made acceptable classifications in blood grouping. Closely upon this followed the epoch making achievements of Carrel, Crile, Lindemann, Huston, Weil, Lewisohn, and Agote. Thus, blood transfusion and the administration of medicaments into the circulation have advanced simultaneously.

Although intravenous therapy is now a well established method of administering drugs to the human organism, and amply supported by clinical evidence, some authorities still maintain that the introduction of therapeutic agents into the veins for the cure of disease is unwarranted, unscientific, and a dangerous practice. This would seem unjust *ipso facto* that the intravenous use of such drugs as arsphenamine, mercurochrome-220, antimony and potassium tartrate, gentian violet, flumerin, fuchsin (medicinal), and acriflavine, the most potent, yet the most toxic of drugs, have proved invaluable in the treatment of disease; and cannot with safety and efficacy be administered in any other way.

It is perhaps true that in intravenous therapy, as well as in the oral, hypodermic, and intramuscular administration, many drugs are given without knowledge of the true pathological condition or definite indication. The fault is not in the method but with the physician. It is as absolutely essential for a physician to know the therapeutic and physiological effect of a medicament used intravenously as by any other method. A knowledge of biochemistry and mastery of technic are also necessary to successful treatment by this method.

The period of two decades of therapeutic nihilism in this country undoubtedly had a constructive effect on therapeutics. It led the profession from the empirical to the more specific methods in therapy. For this reason it is difficult for many to grasp the

rationale of present day methods. With increased knowledge of the technic of using drugs, with the development of pharmacology in its true relationship to pathological variations in the organism, it seems reasonable that intravenous injections will be limited to certain chemotherapeutic classifications. This advancement will tend to avoid the accidents and disappointments that must follow the abuse of a method which rightly employed may be a health making and life saving measure.

Investigators agree that drugs administered by mouth, subcutaneously, or intramuscularly undergo certain modifications in the normal human organism, and in pathological conditions frequently change in chemical constituency. They are also cognizant of the fact that an inhibited peripheral circulation is not conducive to a rapid general dissemination of drugs given hypodermically.

In cases of known pathology, drugs such as arsphenamine, iron cacodylate, sodium iodide, mercury bichloride, quinine, iodine, sodium salicylate, antimony and potassium tartrate, diuretin, hexamethylenamine, when indicated, should be administered intravenously to secure definite results.

It is not maintained that all drugs should be given intravenously, but when admissible and properly prepared they can be used with impunity.

The question is asked, "What is gained by choosing the intravenous method in the use of drugs?"

The following is submitted: a, Accuracy of dose, b, ease of administration, c, maximum potency in a minimum of time, d, control of patients, and, e, definite results.

Then follows the question, "Is there any evidence that they are more efficacious administered in this way than by the mouth or under the skin?"

A number of diseases, with remedies, are enumerated which allows the reader to make his own inference: Acidosis, sodium bicarbonate, gum acacia in glucose, in diabetics and others when unable to retain by mouth; actinomycosis, potassium iodide, sodium salicylate; anthrax, antianthrax serum; anemia, iron cacodylate, citrate solution, germanium dioxide; bilharziasis, antimony and potassium tartrate; botulism, strophanthin, antitoxin; bubonic plague, Yersin's serum, antiplague serum (Pasteur); cholera, sodium bicarbonate, sodium chloride, calcium chloride; filariasis, sodium antimonium tartrate, colloid antimony sulphide; granuloma inguinale, antimony and potassium tartrate; keloid, fibrolysin; leishmaniasis, antimonium tartrate; leprosy, sodium gynocardate, sodium morrhuate; lobar pneumonia, quinine and urea hydrochloride, serum free solution of pneumococcus antibodies, caffeine, sodiobenzoate, adrenalin in normal salt solution; mercurial poisoning, acute, Fischer's solution, calcium sulphide; pulmonary spirochetosis, iodine, guaicol, fuchsin (medicinal); pyelitis, hexamethylenamine, electrargol, mercurochrome-220, acriflavine; septicemia and pyemia, iodine, electrargol, mercurochrome-220, gentian violet, collargol, magnesium sulphate; shock, colloidal gelatin and sodium chloride, epinephrine in saline solution, strophanthin, caffeine, sodiobenzoate, digitan, strychnine; syphilis, arsphenamine, calcium acetylsalicylate, antimony and potassium tartrate, sodium or potassium iodide, tryparsamide, mercury bichloride, flumerin; tetanus, antitoxin; typhus fever, serum, chlorine water; trypansomiasis, tryparsamide; yellow fever, Noguchi's serum, chlorine water, saline and sodium bicarbonate solution; yaws, mercuric chloride, arsenous iodide, sodium iodide; Rocky Mountain fever, serum; goitre, Lugol's solution; osteomyelitis, Credé's colloidal silver, gentian violet, iodine, mercurochrome-220.

The following are references to physicians whose scientific attainments cannot be questioned: Rosewater, Farrar, Vander Veer, Dickinson, Bateman, Fairly, Eichhorn, Regan, Bowcock, Rowland, Christopherson, Pavy, Petillo, Dickson, Howitt, Graham, Schwartzer, Heggs, Blackfan, Sellards, Chatterjee, Adler, Leonard Rogers, Horwitz, Randall, Rundal, Smare, Beck, Neuhof, Baliss, Neilson, Orlando, Schamberg, Greenbaum, Brachio, Fox, Mackie, Piersol, Bockus, Stevenel, Muir, Harper, Brahmacheri, Knowles, Conner, Litchfield, Stengel, Stevens, Wells, Blankenship, Haskell, Carder, Coffendaffer, Weiss, Burmeister, Reasoner, Nichols, Risquez, Hill, Colson, Young, Necker, Archard, De Castro, Gupta, Piper, Kiehne, Louros, Hogan, Lewis, Cornioley, Kotzareff, Crile, Henderson, Hazra, Boas, Harrison, Lovenz, Loevenhart, Blackwen, Hodges, Stokes, Sezary, Pomart, Walker, Ashhurst, Cammert, Freedlander, Matthias Nicoll, Danieloplu of Bucharest, Brown, Pierce, Low, Newman, Marshall, Fischer, Linser, Rosenbeck, Wolf, Spittel, Noguchi, and Park. These names are given in sequence as the diseases and drugs in the preceding paragraph for the reason that these physicians and investigators have presented clinical evidence of the efficacy of drugs administered intravenously in disease.

It has been observed that one patient died from an injection of salt solution, and, also, that "in one of our leading hospital clinics, intravenous salt solutions are prohibited except in emergencies, hypodermoclysis being the approved practice. A hypertonic or hypotonic solution is capable of profoundly disturbing the salt balance in the blood and doing harm, whereas no such harm exists when the solution is given under the skin." Here, again, a knowledge of the pathological condition is necessary. Why give salt solution if it is not indicated?

Since June, 1903, I have given over three hundred thousand intravenous injections including one hundred and forty drugs administered in one hundred and thirty diseases. During the school year 1922-23 and 1923-24, in my classes in intravenous therapy at the Graduate School of Medicine, University of Pennsylvania, I exemplified the efficacy of this method of treatment in the most serious cases obtainable from the wards of the Polyclinic Hospital.

In the period of years from 1903 to date, I have not had a death due directly or indirectly to a drug administered intravenously. Many of my colleagues have given over one hundred and fifty thousand injections without a fatality. This, I am sure, compares favorably with any other form of therapy.

A survey of the activity of the medical practitioners of the United States will reveal that recent graduates are using intravenous therapy extensively and with excellent results. This, in my opinion, confirms the high estimate accorded the profession of our country by our foreign neighbors.

I admit that it is as dangerous to place potent drugs for intravenous therapy in the armamentarium of an ignoramus as to trust a fool with a can of nitroglycerin. Thanks to the high standard of medical education in the United States, there are few of this class remaining to ply their nefarious business!

It is my belief, which is based on experimental and practical experience, that intravenous therapy properly applied will open the gateway to a fertile field of constructive effort in the treatment of disease and will eventually revolutionize the practice of medicine.

THE INTRAVENOUS NEEDLE

William A. Steel, M.D.
Philadelphia

Successful intravenous therapy depends on two things: a properly sharpened needle and an educated tactile sense. Delicacy of touch can only be acquired through experience. Needles should be personally sharpened, and receive the care given to other delicate surgical instruments.

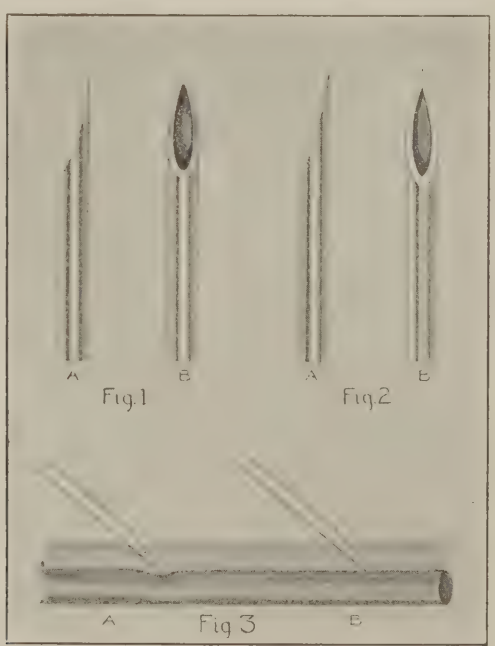

Fig. 1.—Point of the intravenous needle as furnished by the manufacturer. Showing A, the concave bevel edge with resulting shoulder, and B, the tendency to an obtuse chisel point.

Fig. 2.—Properly sharpened intravenous needle with A, a straight bevel edge without shoulder and B, an acute point.

Fig. 3.—Degree of skin and vein wall resistance to the point and shoulder of the commercial needle, A, and to the properly sharpened needle, B.

Hypodermic needles as furnished by the manufacturer are unfit for smooth accurate intravenous work. This is especially true of the larger calibres used in blood transfusion. The commercial needle is sharpened on a small stone wheel, which cuts the beveled edge as a concave surface, and tends to make a chisel instead of an acute point (Fig. 1A and B.) Puncture of the skin and vein wall with such a point requires force and the needle goes through with a jump. When the beveled edge is half way through, the shoulder on the concavity presents itself; more force is necessary, and a second jump occurs. (Fig. 3A.) This irregular jerky puncture has a tendency to push a small vein to one side or to perforate and go directly through a delicate vein. It also gives pain to the patient.

The ideal needle should have an even acute point and a straight flat bevel (Fig. 2 A and B). There is no jump as it goes through the skin or vein wall. The sensation is that of skin puncture by a fine, sharp bistoury. The feel of the needle entering the vein is accurately communicated to the finger. A hard oil hone is the best stone for working down a flat bevel and sharpening the acute point.

300 North Broad Street.

Atropine Therapy.—M. A. Leavitt (*American Journal of Surgery,* January, 1924) says that in a large general hospital, where the anesthetist is frequently confronted with a case on the etherizing table that has a proper setting for respiratory sequelæ to complicate the ether anesthesia, she believes that forced doses of atropine given for forty-eight hours have helped to mitigate the symptoms and sometimes possibly to check them from developing.

Treatment of Hodgkin's Disease.—William S. Stone (*Canadian Practitioner,* March, 1924) says that the x ray and radium are only palliative agents in the treatment of Hodgkin's disease. Palliation can be accomplished in sixty per cent. of cases, and complete restoration of health with or without complete regression of the tumors may result in about thirty-two per cent. Restoration of health will often last for a year and rarely two, three, or four years. Palliation, if it is to follow, will begin after the first or second treatment. Life may be prolonged one or two years.

Simple Treatment of Hiccup by the Production of the Sneezing or Vomiting Reflex.—T. Hishikawa (*Schweizerische medizinische Wochenschrift,* April 10, 1924) recommends two simple procedures for the inhibition of hiccup. The first method is to produce a sneezing reflex by irritating the nasal mucous membrane with a thin feather or a narrow strip of paper. The second method consists in producing a vomiting reflex either by the administration of digitalis or by mechanically irritating the pharynx.

Anthrax and Its Treatment—H. E. Santee (*Annals of Surgery,* September, 1923) sums up his findings as follows: Thirty-seven cases of anthrax are reviewed. This disease tends toward a septicemia from the local lesion. Specific serum offers a very fair prognosis. Its use should be intensive, both intravenous and local, at the outset. Surgery has no place in the treatment of the lesion. Its use may be directly harmful.

Abdominal Tuberculosis and Intestinal Stasis

JAMES TAYLOR, F.R.C.S. (Edin.)

Glasgow, Scotland

It is many years since Sir Arbuthnot Lane said that there was no tuberculosis without previous intestinal stasis, and this remark suggested to me an inquiry into the evidence of stasis in cases of abdominal tuberculosis, and the effect in these cases of measures for the relief of this static condition. I have now investigated twenty-four cases, and while I hope at a later date to deal with the subject more fully, I think the results of the treatment adopted are such as to warrant the publication of a preliminary report.

The cases under consideration are those which are commonly called, and usually notified as, tuberculous peritonitis, but while the peritoneum is probably involved in every case, the term covers an infinite variety of pathological conditions, and in many of the cases the changes in the peritoneum are of comparatively slight importance. In eleven cases the peritoneum was greatly congested, studded all over with tubercles, and many adhesions were present. The mesenteric glands were the parts chiefly affected in another eleven cases. There was one example of ileocecal tuberculosis, with great thickening and infiltration of the bowel, and fixation to the surrounding parts. In one other case the small intestine was extensively ulcerated and greatly deformed. The patients were all in Robroyston Hospital and Sanatorium and some of them had been under treatment there for a considerable time, without undergoing any material change.

Perhaps I may be excused if I state briefly the means by which any delay in the emptying of the bowel becomes such a serious predisposing factor in abdominal tuberculosis, although it is the same mechanism which has been described so many times in connection with other diseases. The fault is primarily in the colon, which, failing to empty with normal rapidity, becomes overloaded, and by its weight tends to fall downwards. Nature in her effort to prevent this ptosis, develops certain bands which attach themselves to various parts of the bowel, and although they are beneficent in their first effect, they tend later to increase the trouble. The bowel becomes kinked at the points where the bands are attached and obstruction with further delay results.

This stasis predisposes in two ways to tuberculous infection of the alimentary tract. The toxemia which is caused by the absorption from the intestine devitalizes the tissues of the body generally. The intestinal wall shares in this poisoning process, and becomes more liable to infection with the tubercle bacillus, to whose attacks it is almost constantly exposed. Again the general delay in the passage of the bowel contents exposes the wall of the intestine to repeated trauma, which is all the more serious as the proliferation of organisms is also facilitated by the stasis and small lesions in the mucous membrane resulting from injury and infection pave the way for the onset of the tuberculous process.

It seems a fallacy to suggest that stasis is present in these cases, as the symptoms usually complained of are rather too rapid emptying of the bowel, and x ray examination confirms this quick passage of the intestinal contents, but at the same time shows a relative delay at certain points. Doubtless if one could have x rayed the patients before the tuberculous infection had taken place, it would have been possible to show that there was a period during which there was actual delay. But apart from indicating the points at which there is still some control of the passage of the meal, the x ray is helpful for distinguishing between the cases that are suitable for operation and those that are not.

X rays showed the barium meal scattered diffusely through the small intestine, five hours after it entered the stomach. In practically all cases which give this appearance, adhesions are so universal that it is impossible to define the relations within the abdomen, in fact it may be impossible to open the peritoneal cavity. A somewhat similar picture was seen in a case of extensive ulceration of the intestine, without many adhesions, but in this case, while there was a considerable amount of the barium scattered through the loops of the small intestine, a large amount had passed into the ascending or transverse colon. A third plate showed the usual appearance in a case with an ileal control, and in which one would expect a good result from operation.

The points of obstruction were invariably those described by Lane in his book on intestinal stasis,

namely, one under the pelvic colon, the first and last kink, and the other at the terminal ileum. The obstruction at the latter point was caused in most of the cases by a controlling appendix, that is, an appendix fixed by a band under the last part of the ileum, in such a way that with the drag of the cecum on one side and the loops of small intestine on the other, the last part of the small bowel is acutely bent over the cord which the fixed appendix represents. In the other cases, with one exception, there was a well formed band close to the cecum and under the ileum, fixing this part of the bowel, and sometimes rotating it markedly on itself.

Of the twenty-four patients operated on, in seven the adhesions were so diffuse that it was impossible to examine the relations of the various parts of the intestine, but of the remaining seventeen there was no case that did not show definite evidence of the formation of bands, extremely faint in some of the young children, but quite easily defined. There was a definite band under the pelvic mesocolon in every case but one. This exception was a child of three with a long mobile loop of pelvic colon. The band under the ileum was present in six cases, and all the others had controlling appendices. One child of two years had a first and last kink, an ileal band, and a controlling appendix.

The operation performed was a careful division of the bands, freeing the bowel and allowing the fixed loop to be straightened out, followed by accurate suturing of the peritoneum over the raw surfaces. The controlling appendix was removed at the same time.

Case I.—S. R., aged seventeen, was admitted complaining of pain in the abdomen of five months' duration. There had been one attack of diarrhea followed by constipation which persisted till admission to hospital, when it was found that the bowels only moved in response to doses of cascara and liquid paraffin. The patient was emaciated, the abdomen retracted and resistant. Laparotomy was performed when a well marked band under the pelvic colon was divided. A band under the ileum causing marked rotation of the bowel, was also divided, and a retrocecal appendix removed. After the operation the bowels moved without any aperient, and the patient put on thirteen pounds in a month. She was dismissed from the hospital well.

Case II.—B. L., aged seventeen, was admitted complaining of amenorrhea and abdominal pain. The bowels were inclined to be constipated. The patient was rather flabby and fat, and the abdomen resistant. No masses could be felt, but there was well marked tenderness over the terminal ileum. After resting four and a half months the pain had gone but otherwise the condition was unchanged. Laparotomy was than performed, and both visceral and parietal peritoneum were found studded with tubercles. There was a large mass in the lower abdomen consisting mostly of infiltrated omentum. A dense band passed from this mass to the left parietal wall, compressing the pelvic colon. This band was divided and the sigmoid loop raised. A band under the pelvic mesocolon was then divided and the raw surface peritonized as well as the infiltrated and friable peritoneum allowed. A controlling appendix was also removed, although there was considerable infiltration of the parts around. Three months later the patient was discharged feeling perfectly well. She was thinner and much healthier looking. Menstruation which had been in abeyance for seven months returned soon after the operation and was regular till she left hospital.

Case III.—T. O., aged nine, was admitted with a discharging tuberculous sinus over the lower third of the thigh. There was no evidence of disease of bone, but he began to lose weight rapidly till at the end of two months he had fallen from sixty-five pounds to forty-two pounds. The bowels were constipated but he had an occasional profuse watery stool. He vomited at frequent intervals. Laparotomy was then performed an dextensive ileocecal tuberculosis found. In his exhausted condition resection was out of the question. There was a dense controlling band under the pelvic colon, which was divided and the raw surface peritonized. Improvement began at once. The sickness stopped and he steadily increased in weight till at the end of six months he had reached sixty-six pounds.

Case IV.—W. W., aged thirty-six, admitted complaining of pain in the epigastrium and diarrhea of four years' duration. The pain was always worst about half an hour after food and was accompanied by occasional vomiting. The abdomen was distended and rather tender in its lower half. Laparotomy was performed and advanced tuberculous disease was found in the lowest two feet of the small intestine. There was evidence of extensive ulceration of the bowel with much deformity, the bowel being constricted at various points, and ballooned at others. The pelvic colon was long and there was a well developed band on the under surface of the mesocolon, and another controlling the end of the ileum. These bands were divided. The patient's condition gradually improved. He had little pain almost from the first, and at the end of four months only very occasional diarrhea. These cases are types of the various conditions dealt with, and although in every case the results were not as striking as these I have described, in all but one there was definite improvement where obstructing bands were divided. Even among quite young children, who had only the earliest stage of secondary change, the improvement was distinct. Their diarrhea was less marked or disappeared entirely and they were altogether brighter and happier. No doubt all their organs became healthier, when their drainage system was improved and they were freed from the intestinal toxemia. Yet the operation was comparatively simple and one would not expect its results to be phenomenal. Even in the cases with the densest bands and the most severe kinking the lumen of the bowel was not much narrowed. I can only suppose that the peristalsis of the bowel is interfered with in some way, in any case there is no doubt about the marked effect on the patient of the operative correction of these partial obstructions.

Dr. White Robertson has pointed out the effect of the master toxin—usually an intestinal toxin—in cases of tuberculous disease, and Mr. Morriston Davies in his lecture on Pulmonary Tuberculosis and Intestinal Stasis, has shown that many of the febrile attacks to which phthisical patients are subject are due to an exacerbation of their intestinal toxemia as demonstrated by an increase of the sulphoethers in

the urine. He has also shown that if a reaction is to be avoided in treating cases by artificial pneumothorax, the patients must be prepared beforehand by the clearing out of the bowel, and the administering of intestinal antiseptics, and toxin adsorbents like kaolin. I have noticed also that the digestive troubles among pulmonary cases are frequently the direct result of intestinal stasis. In some of the more severe cases of sickness and vomiting, cases which refused to respond to medicinal treatment, I have seen the gastric symptoms entirely disappear after the division of bands at the terminal ileum and the pelvic colon, and without any interference with the stomach itself.

In young children I should think that medicinal treatment for the stasis would usually be enough, as only the earliest changes in the bowel have taken place, and marked controls have not developed. In the group of cases I have described the benefit resulting from the operation was, as a rule, in proportion to the age of the patient, because the longer the stasis had been going on, the more marked were the secondary changes, and the greater the need for operative relief.

I am indebted to Dr. John Watson for permission to use the hospital records, and for his kindness in facilitating my work. I also have to thank Dr. Fergus Henderson for the radiographic examination of the cases.

Certain Types of Advanced Tuberculosis; an Economic Asset

LeROY S. PETERS, M.D.
Albuquerque, New Mexico
Medical Director, Saint Joseph Sanatorium

After the discovery of the tubercle bacillus by Robert Koch in 1882, the medical profession felt that, knowing the causative factor in the disease, it would be only a matter of a few decades when tuberculosis would be as rare as smallpox after vaccination was given to the world by Jenner. All that remained to be done was to keep the active cases from spreading infection from one to the other, and this could so easily be accomplished by a campaign of education fostered by such an association as our own national organization.

The failure to stamp out tuberculosis is only too well known to need comment. The failure to find a specific to cure the already existing cases is likewise medical and general history. It took the profession years to learn that the educational campaign must be directed against the infant in arms if it was to curtail even to a small extent the development of adult tuberculosis.

Not only in the prevention of the disease have we been slow to hit at the fundamentals, but equally so in our education of the physician in the essentials of an early diagnosis. Too often is the early type case sent from the doctor's office with a pat on the shoulder and with the assurance that there is nothing wrong with him—only to have the disease make deeper inroads into the already infected lung, and turn this favorable and curable case into one that is probably doomed to failure.

In the past this has been due to lack of interest in our medical schools. To advocate the teaching of tuberculosis was to provoke a smile and to even hint at the necessity of a chair or a department where the student might learn the principles of diagnosis, was to argue one's fitness for an asylum.

Times are changing, and the better schools are turning their attention to a study of the disease, and year by year students are graduated with at least a working knowledge of physical diagnosis. Yet, today, the percentage of early cases is on the wrong side of the ledger. In the Southwest sixty per cent. of our admissions are in the far advanced stage of the disease.

Tuberculosis, to be cured or properly arrested, must be taken early, otherwise we are merely prolonging a life of invalidism. Yet the percentage of recoveries in advanced disease is so surprising that we must needs devote our attention to that large class of patients who have been permitted to reach that unfavorable classification.

Incipient tuberculosis is cured in the majority of cases; moderately advanced in less numbers, and far advanced cases offer but a piteously low percentage of real arrests. Yet, as I have stated, that class is the one with which we are overwhelmed, and the class which taxes the wits of the physician who comes in contact with its countless hordes. To look wise and give a fatal prognosis is not the mission of the honest practitioner of the healing art. The problem must be attacked from all angles; yet, how many of us have faced it from a practical viewpoint?

When I began the practice of tuberculosis as a specialty, I was inclined to keep the far advanced patient under sanatorium care as long as possible, never daring to permit him much leeway in exercise; and only when it became an economical question did I dare face the issue. The result was disastrous. Here was a man who had been kept indefinitely on the rest cure, suddenly thrown upon his own resources—forced to make a living for himself and family, and ill prepared for the emergency. It required but a short time to undo all the good that had been done by the sanatorium care and treatment. He relapsed—there was no other way out.

Gradually, as years went by and patients came under my observation who had been working years with advanced disease—only to discover their trouble by an x ray or by accident, I became bolder, and screwed my courage to the sticking point, attempted slowly and with infinite care to get this class of subjects back somewhere near a normal existence.

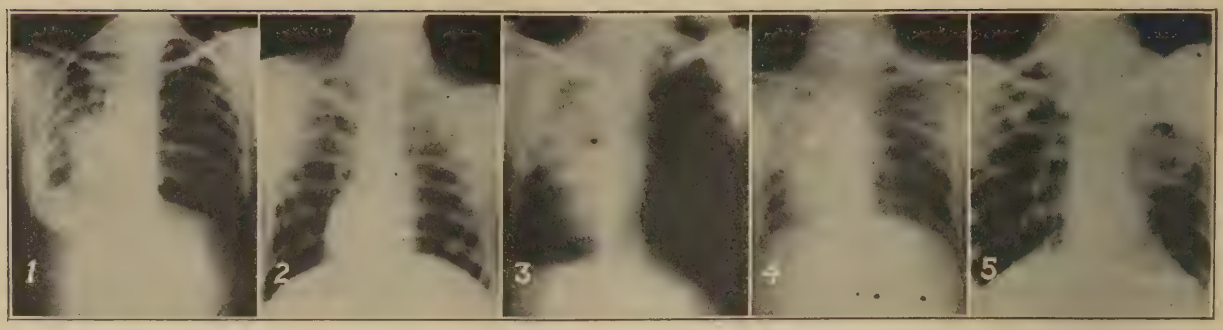

FIG. 1.—Case III FIG. 2.—Case V FIG. 3.—Case VI FIG. 4.—Case VIII FIG. 5.—Case XI

The results were surprising, and as I hope to show you with the appended case histories, well worth while.

Do not misunderstand me—and I know of no other class of people who misunderstand more than physicians. I do not advocate graduated exercise for all cases of advanced tuberculosis, neither do I advocate this to the exclusion of a properly carried out rest cure. The rest cure must come first always, but understand this—that the rest cure must not be carried out indefinitely, if we are to ultimately get a satisfactory result. It is easy to fall into the habit of keeping advanced cases in institutions two, three, four and five years—if they live that long—at bed rest. They are little worry to the medical staff, and they help keep the beds full and raise the length of stay in a given institution. I know, for in years long past I have tried it with this result. But that is not restoring the individual to society. It is merely prolonging an invalid life at the expense of society, and the majority of people I find are glad of the opportunity to test themselves out, to determine whether they are ever to regard themselves as an asset or whether they are to continue existence as a liability. True, occasionally one finds a patient who feels that life in bed is a continuous round of pleasure, but that person is the exception rather than the rule.

How shall we determine rest or exercise in a given patient? Remember, I am speaking of far advanced tuberculosis only, and refer to the individual who has a fair attempt at fibrosis, and do not consider the hopelessly sick consumptive.

First of all, we need a thorough history. Almost as much, if not more, information can be gained from this in forming our conclusions as to the patient's ability to do things, than from any other source. Then there should be a period of observation at comparative rest until patient and physician know each other.

The physical findings should exclude as far as possible activity of the process, but it is my opinion that clinical signs of activity in these cases are more important.

The physical examination of these chests by the average man would keep these patients, who are doing full time work, in bed the remainder of their lives. Most of them are filled with coarse type râles and crepitations over these fibroid areas, which are indefinitely persistent. Case XVII was under observation of the Veterans' Bureau in Albuquerque, and after I had given him unlimited exercise for six months, they told him he still had a great amount of activity, but by great care he might attempt one meal a day in the dining room!

Having determined these factors, meals in the dining room are first tried out—one meal, then two, then all three. No other exercise is given at this time. After trying this for a month, a short walk of five minutes' duration daily is prescribed, which is then gradually run up to full time. Patients who like golf can be relieved of aimless walking by nine to eighteen holes daily. Finally—if they remain with one long enough—I want six months of normal life under close observation.

This method of restoring to lives of usefulness the far advanced tuberculous subjects will not always prove successful. Many times we will attempt it to find it cannot be done, but if the cases are carefully selected, success is more often encountered than failure, and another human being is snatched from a life of invalidism.

The appended cases are selected at random from our records at St. Joseph's. These could be augmented many times, but space forbids. They are typical of the class for which I ask your consideration. In studying the records, remember none of these patients can be considered apparently cured. All have cough and sputum, and in all, the sputum is

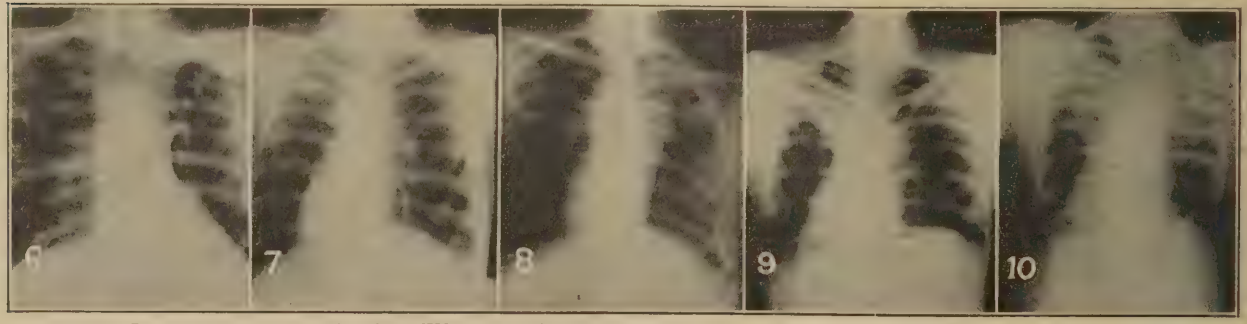

FIG. 6.—Case XII FIG. 7.—Case XV FIG. 8.—Case XIV FIG. 9.—Case XVIII FIG. 10.—Case XXI

positive for tubercle bacilli. Six live in the middle West, four live in California, and the remaining twelve in the Southwest plateau region. We have simply restored a fair degree of physical health, plus a certain amount of fibrosis, and given the individual a chance to live a life of usefulness rather than suffer an existence of invalidism.

Case I.—Admitted September 23, 1920, aged twenty-five. History dated back from July, 1917. Discharged from army because of active tuberculosis. Chest findings showed entire involvement of right lung and upper left through second rib; few râles after cough over these areas. Discharged, arrested September 26, 1921. Has practised law in Albuquerque ever since with no return of activity, chest shows excellent fibrosis with no râles anywhere.

Case II.—Admitted May 31, 1922, aged twenty. History dates back from September, 1921. Chest findings: fibroid tuberculosis both uppers, and râles after cough in these areas. Discharged from sanatorium, improved, May 15, 1923, with exercise up to one hour time daily. Has lived in the city, gradually increasing exercise up to normal life, which she has led past year with no aggravation of symptoms. Married first part of 1924. Chest still shows crepitations left upper.

Case III.—Admitted December 2, 1921, aged twenty-eight. History dates back to spring, 1920. Pulmonary hemorrhage in March, 1921, (twelve in series). Second series October, 1921. Findings: Complete involvement of acute type entire left and central right. Numerous râles increased on cough. Discharged June 1, 1922, improved, to live in the city. Graduated exercise after three months in the sanatorium, up to normal life in six months, which she has followed since. Does her own housework, and enjoys fair degree of health. Chest still shows a great deal of moisture, but the râles are mostly bronchial.

Case IV.—Admitted June 28, 1920, aged twenty-two. History dates back three years. Findings: Complete involvement left upper, large cavity second interspace, râles increased on cough. Exercise gradually increased until June 3, 1921, was leading normal life, and has continued to do this past three years. Chest still shows large amount of fibrosis, with crepitations over posterior portion.

Case V.—Admitted June 1, 1922. History dates back four years. Had followed cure faithfully at bed rest most of that time due to the fact that his physician considered his chest active because of the large number of adventitious râles heard on auscultation. Findings: Involvement left upper and right upper and middle lobes. Crepitations over these areas. Advised graduated exercise at once. In three months was taking one hour walk twice daily, auto rides, etc.; but returned to warmer winter climate where his former physician immediately put him to bed because of so much activity. Was kept at rest all winter, returning to me the following spring, and again we began graduated exercise. By the fall of 1923, he was leading a normal life, with no return of symptoms. At present he is conducting a radio supply house in Albuquerque—married, and has become a useful citizen again. Chest still shows crepitations in both uppers.

Case VI.—Admitted October 4, 1920, aged thirty-eight. History dates back five years. Old fibroid tuberculosis involving entire left lung with cavity formation in upper right. Crepitations over left lung, but none in right. This patient went to Colorado in 1916 where he was kept on the rest cure for four years. By February, 1921, he was taking fifteen minutes' exercise twice daily which was gradually increased, so that on discharge July 12, 1921, he was leading a normal life. He went to Colorado and has been practising law ever since. Chest findings on discharge same as on admission.

Case VII.—Admitted December 17, 1918. History dates back one and a half years—with hemorrhage. Chest showed involvement both uppers with subcrepitant râles increased on cough. Discharged from sanatorium August 8, 1920, condition quiescent. Began work and had another hemorrhage. Rested one month, resumed active life and has been working past three years with no increase of symptoms. Chest still shows crepitations over right upper and over right base posterior, and left upper.

Case VIII.—Admitted January 1, 1922, aged thirty-three. History dates back four years. Old fibroid tuberculosis entire left with large cavity below clavicle. Crepitations upper right over all fibroid areas. Had been kept at bed rest in a middle western institution and given a hopeless prognosis because of the extensive involvement. Decided to make a change to the Southwest, and after a short observation, was given graduated exercise, and in one year was leading a normal life. He opened a store in Albuquerque which he ran for a year, and then accepted a position as manager of a large clothing concern. Condition is excellent, although chest findings are the same as on admission.

Case XI.—Admitted June, 1920. History dates back four years. Took treatment at home during this time. Came to Albuquerque and at once began work, which he has followed ever since, except while confined several times for hemorrhages. Is employed as gardener at St. Joseph's where of course he is under constant observation. Chest shows fibroid tuberculosis with cavitation. Numerous râles over both lungs.

Case XII.—Admitted January, 1911, aged twenty-eight. History dates back five years. Was under treatment three years. Rest one year, graduated exercise and normal life at end of two years. Has been working constantly for past ten years. Chest shows same physical findings today that it did ten years ago, viz., evidence of fibrosis over both lungs especially left, and numerous coarse type râles over entire left lung.

Case XIV.—Admitted May 17, 1921, aged forty. History dates back but six weeks. Chest: Old fibroid tuberculosis of long standing involving right upper and middle lobes, with cavity upper, second interspace. Infiltration left upper to third rib and sixth dorsal spine. Coarse râles over right upper and middle lobes, and subcrepitant râles over left increased on cough. The left lung apparently was giving him acute trouble.

Patient was put on bed rest, temperature came to normal in short space of time, and in twelve months he had gained forty-five pounds in weight.

Graduated exercise started within two months of admission, and he was leading a normal life at time of discharge March 17, 1922. Returned to work in Oklahoma as traveling salesman, but in five months had an attack of pain over appendix region. Came back and a hard tumor mass was felt in this area. After gastrointestinal series of plates were made, a diagnosis of cecal tuberculosis was made; later confirmed by Dr. Archibald of Montreal. He advised against operation. Patient was kept at rest for three months, and then graduated exercise started again—increased slowly to normal life, which he has led since fall of 1923 with no return of abdominal symptoms. Now he is in California and works as traveling salesman. Chest shows dense fibrosis right upper and middle, with crepitations over upper lobe.

Case XV.—Admitted August 29, 1918, aged thirty-four. History dates back eight years. Tuberculous peritonitis in 1917. Operated and tuberculous ovary and appendix removed. Urine: casts and albumin. Chest findings: fibroid tuberculosis both uppers with râles increased on cough. Chest quiescent in one year's time, and graduated exercise up to fairly normal life by time of discharge June 1, 1920. Since then has lived normal life in California with no aggravation of symptoms. Chest shows fibroid tuberculosis both uppers with crepitations over these areas.

Case XVIII.—Admitted April 15, 1921, aged thirty-three. History dates back three years. Chest findings on admission: Fibroid left lung, with cavity second interspace. General infiltration right upper; râles of coarse type over left and subcrepitant râles over right upper. Given graduated exercise after six months. Discharged quiescent April 25, 1922, and has since lived in Pennsylvania with no increase of symptoms. Supervises her housework and cares for a family of three. Chest on discharge still showed coarse râles left upper and crepitations over right upper.

Case XXI.—Admitted March 15, 1917, aged fifty-two. History dates back six years. Chest findings: Fibroid tuberculosis both uppers with râles increased on cough. Discharged quiescent August, 1918, and has since lived a normal life in Iowa, with no increase of symptoms. Chest findings have remained same as on admission in 1917. Verified by us in 1921, and by reports since.

Regardless of the differences of opinion on climate, the patient discussed in this report lives better and longer with his tuberculosis in the arid plateau region of the Southwest, than a person of the same type can possibly do in climates which are less favorable.

[1]Cases IX, X, XIII, XVI, XVII, XIX, XX, and XXII have been omitted on account of lack of space. They will appear in the author's reprints.

Indications for Thoracoplasty in Pulmonary Tuberculosis

J. BURNS AMBERSON, Jr., M.D.
Loomis Sanatorium, Loomis, N. Y.

Increasing experience and improved methods of observation are constantly making easier the great problem of prognosis in pulmonary tuberculosis. There is still much to be desired in this direction but, by using data which can be assembled in almost every case, it is possible to follow reasonably closely the undulating state of relative immunity, and often to anticipate the anatomical changes of destruction and repair. The process of healing can be traced by clinical and roentgenographic observation from inception to ultimate completion, and where effective healing is not attainable naturally, this fact can usually be recognized before it is too late to resort to the aid of artificial measures of proven value.

These measures, which are numerous and of variable worth, are included for the most part in the general domain of collapse and immobilization therapy. The rationale of inducing lung collapse by one means or another to promote the healing of tuberculosis is now well understood by most physicians treating this disease, and the results obtained amply justify it as the most important adjuvant to the standard hygienic rest treatment. Its position has been established primarily by the extensive practice of artificial pneumothorax. Valuable as this proved from the date of its introduction by Forlanini and by Murphy, it did not require many years to demonstrate that in a considerable percentage of cases, although anatomically suitable, collapse of the lung is hindered or prevented by the presence of pleural adhesions. As a logical evolution, therefore, attempts were soon made to effect collapse by other and more drastic methods; chief among these is thoracoplasty—resection of a few to eleven ribs allowing one side of the thorax to sink, and thus indirectly bringing about the desired collapse at least in part. The Germans have been the leaders in perfecting and applying this procedure, Sauerbruch alone having seven hundred operations to his credit. As in using artificial pneumothorax, American clinicians have been slow to adopt the method on a wide scale. It is now growing rapidly in favor, as a study of the literature will prove, and, in a strictly limited group of cases, is certain to take its place as a standard aid in treatment.

By those who have had the largest experience it is estimated that from ten to fifteen per cent. of all patients with pulmonary tuberculosis should be treated by some form of collapse and immobilization therapy; at the Loomis Sanatorium where many advanced cases are received the latter figure is approached. In more than half of these the simpler procedure of artificial pneumothorax is adequate. Sauerbruch declares that five per cent. of all cases are suitable for thoracoplasty, and, in a recent review of the subject, Alexander (1) estimates that in the

United States there are now fifteen thousand persons with pulmonary tuberculosis for whom surgical interference is indicated. With this may be contrasted Alexander's finding of 1,024 cases of operation reported from 1918 to 1923.

The operation now usually employed is the Sauerbruch paravertebral rib resection. The complete procedure includes cutting the first eleven ribs close to their vertebral attachments and removing sections from each rib—two to four cm. from the first, and increasing to ten or more cm. from the eleventh. This allows the sectioned ribs to drop and the side of the chest to sink (Figs. 1 and 2). This half of the chest is reduced by one half to two thirds (Saugman), and the lung volume is diminished by three hundred to five hundred c. c. (Sauerbruch and Brunner): where massive fibrosis has previously developed the collapse may be greater. Because of the incompleteness of the collapse it is sometimes necessary to perform supplementary operations, such as a resection of one or two upper ribs anteriorly, or pneumonolysis. Section or avulsion of the phrenic nerve on the affected side with subsequent paralysis of the diaphragm (Figs. 3 and 4) is often done as a preliminary to thoracoplasty: the paralyzed diaphragm becomes immobile (except occasionally for passive movement) in a position a little higher than in normal expiration, and this contributes more or less to the collapse and rest of the lung.

Taking collectively all the thoracoplastic operations which have been performed for tuberculosis, the results have been estimated approximately as one third dead (at operation or due to subsequent complications such as aspiration pneumonia in the better lung), one third improved, and one third arrested and restored to approximately normal lives. Sauerbruch reports thirty-nine per cent. as arrested or "cured." These figures, of course, represent salvage from a group of cases in which the prognosis otherwise was almost uniformly fatal. The hazard is considerably reduced by performing the operation in two or three stages at intervals of a week or more, local anesthesia being preferred in many instances.

Temporary unpleasant effects from the operation include neuralgic pains, cutaneous anesthésias, and circulatory disturbances, but often these never appear. The chest deformity usually cannot be regognized when the patient is clothed. In the type of case usually selected for this operation time has previously elapsed to allow compensatory changes to establish themselves, so that, as a rule, in the favorable, uncomplicated cases, no lasting respiratory or circulatory embarrassment results directly from the operation. With a proper anatomical collapse, healing, which already has been initiated, is allowed to continue unhampered by mechanical barriers, fibrous tissue shrinks and grows more compact, and cavities are further contracted or closed. The symptomatic effect is often remarkable, and even when not completely satisfactory, the patient finds the disability easier to bear and may live longer and more comfortably than would have been possible otherwise.

To define the group of cases suitable for thoracoplasty it will perhaps appear more logical to proceed by elimination, mentioning first the contraindications. The first condition is that an adequate trial of routine rest treatment must be made. This usually suffices in first stage cases in securing a durable arrest of the disease: moderately advanced or second stage cases respond in more than half the instances, but far advanced cases in a much smaller percentage. In favorable cases, healing by absorption and fibrosis occurs, and not infrequently small or moderate sized cavities become contracted or entirely obliterated. Often repair may progress for a period of two to five years or longer before a dependable result is observed. Hence, it is not wise to be tempted to use drastic surgery when the ultimate prognosis appears good without it, the only exception to this being the situation in which, for economic or other reasons, the patient is unwilling to undergo a long period of treatment and prefers to shorten this by assuming the risk of an operation.

Thoracoplasty is not employed when artificial pneumothorax suffices to produce the necessary collapse and immobilization. Even in the presence of pleural adhesions allowing only a partial collapse, air insufflations are not to be discontinued without good reason. Often adhesions can be stretched gradually or are so placed as not to interfere indefinitely; then after patient efforts over weeks or months an effective compression of the lung can be obtained. When unyielding stringlike adhesions interfere with the therapeutic result, some have sectioned the bands by the method of Jacobeus, using the thoracoscope and electrocautery; this, however, entails a risk of pleural infection and empyema twice as great as is involved in the practice of pneumothorax alone, not to mention other minor complications. Thoracoplasty, therefore, is preferable if the lung is badly damaged and adhesions are extensive.

If the better lung must be closely studied before inducing pneumothorax, its status must be even more diligently determined before performing thoracoplasty. It is unusual to find tuberculosis limited strictly to one lung; in most cases at least healed parenchymatous tubercles appear in the better lung. The calcified and fibrotic condition of these deposits can sometimes be determined promptly, in which event, unless spirometric readings show a reduction of vital capacity below fifty per cent. of the calculated normal, they cannot be regarded as a contraindication to the operation. On the other hand a fresh deposit in the better lung, however small, is a deterring sign, and before operation can be advised the lesion must be watched until it is shown that it is dependably nonprogressive and inactive. Intermediate between these two extremes is the largest group encountered, viz., those cases in which small or moderate sized tuberculous masses, quiescent or only partially healed, exist in the better lung. Here delicate judgment is required.

It is always best to defer surgery until one is thoroughly assured that the more diseased lung is not healing and cannot heal naturally and that the lesion in the contralateral lung promises to remain quiescent, although it may continue to cast its shadow in the roentgenogram and give rise to definite physical signs including a few râles which we know persist in healing and healed lesions. In such situations thoracoplasty is usually not contraindicated. The more pressing the need for collapsing one lung the

more risk one must assume with the other or with any extraneous condition which, under less stringent circumstances, would be considered a contraindication; here, the patient must be informed accurately of the situation and his own preference given most weight, since the prognosis with or without operation

Fig. 1.—Progressive chronic ulcerative tuberculosis of right lung treated by artificial pneumothorax. Subsequent perforation of pleura and development of tuberculous empyema with obliterative adhesions.

is usually poor. We have recently had a thoracoplasty done as a last resort in a patient who has a small fibrous walled cavity (less than one cm. in diameter) in her functioning lung, but usually the presence of cavity is an absolute contraindication. We have learned that, after inducing pneumothorax and thereby controlling toxemia and its resulting symptoms, lesions in the functioning lung may proceed to more rapid healing. The same can be expected with thoracoplasty but the initial strain and shock is more severe and the hazard, therefore, greater.

In acute pulmonary tuberculosis thoracoplasty is not advised. Here, fortunately, widespread pleural adhesions have not usually had time to develop, and artificial pneumothorax can be employed in unilateral disease.

Nonpulmonary tuberculous complications are present in most cases of advanced pulmonary disease, and, if so serious in themselves as to impair markedly local function or threaten life, usually contraindicate major surgical procedures. However, the principle suggested above must be kept in mind; namely, that any measure which eradicates or helps to dam up a source of toxemia in one tuberculous focus relieves the opposing forces of bodily resistance against the disease proportionately and contributes just so much to the balance of this resistance against similar sources elsewhere. The observing clinician sees repeatedly the lesions of active intestinal tuberculosis or some other complication subside and become quiescent as lessening toxemia follows the collapse of an extensively diseased lung by artificial pneumothorax. With thoracoplasty, however, the strain of the operation may depress general resistance, and pulmonary lesions may temporarily be stirred up, affecting adversely remote lesions by inducing a focal reaction, which is usually evanescent but occasionally persists. The possible influence of tuberculous complications is, therefore, a matter requiring nice judgment. If one were always intimidated by their mere presence many a patient would be denied the great benefit which the operation often confers, for if the complicating lesion is localized, stationary, or only slowly progressive, and has not seriously damaged local function it is more likely to be helped than hurt following the control of the pulmonary disease by collapse therapy. On the other hand, it is senseless to subject a patient to a major operation when a complication is widespread, rapidly progressive, and of fatal import.

The same principles apply more or less to nontuberculous complications which, however, are not so often encountered. Special attention must be paid to the heart and circulatory system. Fortunately, in cases selected for this operation the heart has previously adapted itself to altered anatomical relationships to which a thoracoplasty will not add a much greater mechanical strain. Naturally, better results are to be expected if cardiovascular tone is not markedly impaired, as determined by blood pressure

Fig. 2.—Same case as in Fig. 1, eighteen months after phrenicotomy, complete thoracoplasty (with later resection of lower ribs over empyema sac), and thoracotomy. Clinical result excellent; loss of all constitutional symptoms sputum scanty; capacity of empyema sac less than twenty c.c. with very slight drainage; patient ambulant and living at home.

observations. In chronic tuberculosis the myocardium is sometimes greatly atrophied, and in such cases thoracoplasty should be advised with caution, if at all. The two or three stage operation, of course, is preferred to the single stage one.

Saugman thinks the operation should not be done

on patients who cannot tolerate a local anesthetic, but when expectoration is slight Sauerbruch has found ether safe.

The indications for thoracoplasty are reasonably positive and clear cut. They exist chiefly in chronic fibrocavernous, predominantly unilateral pulmonary tuberculosis when more conservative measures of treatment have been tried and found wanting. This group comprises four subgroups: 1. The patient with longstanding extensive unilateral disease who, for one reason or another, presents himself for treatment late in the course of his malady. In such a case constitutional symptoms may be of variable intensity but, because of the presence of cavity, cough and expectoration containing tubercle bacilli are almost always chronic and persistent. If the total area of cavitation exceeds four or five cm. in diameter, in spite of previous contraction of fibrous tissue, it is almost sure that complete healing will never occur naturally. If the history of chronic illness with intermittent symptoms is of long duration and these continue unabatingly after a short period of rest treatment, and if no contraindications exist, lung collapse isadvised; pneumothorax failing, thoracoplasty is resorted to.

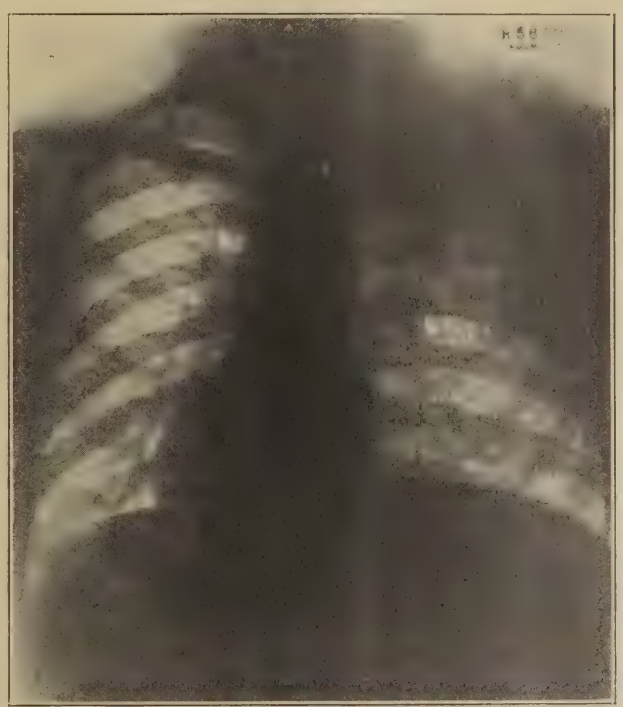

Fig. 3.—Dense fibrocavernous infiltration of long standing in the right upper lobe. Artificial pneumothorax attempted but ineffective (air pocket shown by ring shadow). Symptoms severe; general condition poor; complicating tuberculous laryngitis and enteritis of moderate severity; slight chronic nephritis. Operation offered as a last resort.

2. Cases in which a period of rest or sanatorium treatment has accomplished definite benefit, transforming a subacute or chronic ulcerative and caseous lesion into a fibrocavernous one, but in which symptoms, while less intense, reach a level at which they persist for months or years, and healing is seriously retarded or halted by mechanical barriers (such as large fibrous walled cavities) which are likely to yield only to lung collapse. In other words these cases arrive at the point occupied by subgroup 1. Earlier in their disease major surgery would perhaps have been risky but, having settled down to a state of established chronicity and fibrosis, they are now more suitable for the operation and the need for it is greater.

3. A group of cases in which constitutional symptoms are entirely absent or only intermittently present, but in which, because of the existence of unhealed cavities, there is chronic cough with expectoration. Such patients may go on for years working and without any serious handicap, but the menace of dissemination of the disease and such accidents as hemoptysis is constantly present. Usually lung collapse removes this menace, but whether the operation is to be done depends largely on the patient's attitude. In such cases the surgical risk is least.

4. Cases in which the contraction of massive fibrosis has caused such distortion and displacement of the heart and great vessels as to cause disabling circulatory symptoms. We have had this operation done in one case of this kind, the displacement having developed when artificial pneumothorax treatment was discontinued.

In addition to this group certain cases are met with in which the indications are not so clear cut. Healing and fibrosis may not be so well initiated, yet the need for lung collapse may be pressing and the results are not infrequently good. Here again opposing factors must be weighed and balanced, one against the other, and courage must support the conclusion which is drawn.

In certain instances of intractable hemoptysis, in which pneumothorax could not be induced, a thoracoplastic collapse has been employed. The risks of a posthemorrhagic bronchopneumonia are great.

Some authors lay particular emphasis on the development of bronchiectatic cavities in fibrous tuberculosis as an indication for thoracoplasty; these have practically the same significance as old tuberculous cavities.

In chronic tuberculosis empyema, secondary to natural or induced pneumothorax or simple pleural infection, with a draining sinus of the chest wall, thoracoplasty is often indicated, especially if a patent pleuropulmonary fistula persists. Thoracoplasty and thoracotomy produce a marked reduction of the empyema sac and of its drainage, and occasionally complete healing may occur.

Even though in certain cases pneumothorax treatment is partially successful one or two areas of cavitation may resist collapse and give rise to persistent cough and expectoration. A partial thoracoplasty may suffice to complete the collapse, but in some cases, because of the original extent of the pulmonary lesion, it is best never to allow reexpansion, and, therefore, to advise a complete thoracoplasty.

In the treatment of tuberculosis dogmatism has but a small place. Clinical judgment, born of experience, is a prime essential. In deciding the place of surgical procedures in the scheme of treatment, therefore, none but broad general principles can be laid down. Further experience will define these principles more clearly but always the results will vary with the training of the observer. At no point is it of more importance for the physician and the surgeon to cooperate. The former must study the cases, and determine when and to what degree col-

lapse and immobilization are needed; the latter, in addition to performing the operation, must decide on the type of operation which will best satisfy the needs.

I would warn especially against dissociating thoracoplasty or any similar measure from the broad scheme of phthisiotherapy, and calling it, singly, a treatment or a "cure" without doubt it has its place, but this place is as a mechanical aid in one limited section of the large field. This view is fully endorsed by Howard Lilienthal who has been the consulting and operating surgeon in most cases selected at the Loomis Sanatorium.

Like pneumothorax, thoracoplasty in itself does not remove the tuberculosis. The surgeon sets the stage for better healing; and then, under the supervision of the physician, the patient continues hygienic rest treatment until such healing is attained. To neglect this is to thwart the possible good effects of surgery.

Resolution and Healing in Pulmonary Tuberculosis*

RAPHAEL A. BENDOVE, M.D.
Bedford Hills, N. Y.

It has long been accepted and it is still the orthodox belief of most clinicians and pathologists that healing of the lesions induced by the tubercle bacillus always means sclerosis or calcification, and even standard textbooks fail to mention the more radical view expressed recently by a few phthisiologists that specific tuberculous changes can resolve, heal and disappear completely. Krause (1), who has been vigorously defending this view, states: "that healed tubercle does frequently grave a permanent record in once infected tissues is sound pathological doctrine, but that it always does so is not borne out by facts, clinical or experimental." The complete absorption and disappearance of tubercles on the peritoneal surface is an established fact. The proof of perfect *restitutio ad integram* is demonstrated by carefully planned and serially prosecuted immunity experiments.

Gardner (2) in his admirable contribution Healing by Resolution in Experimental Tuberculosis, has demonstrated clearly with numerous microscopic illustrations that an attenuated tubercle bacillus, known in the Saranac Laboratory as R1 strain, is capable of producing lesions which progress to caseation, and that this caseation together with the accompanying proliferation of fixed tissue cells is then absorbed completely. "The healing process is one of resolution of which no trace remains at the site of the former lesion."

Unfortunately we have no method yet by means of which we could study microscopic tissue reactions and changes *in vivo*, but röntgenography is about the only method hitherto found which will give an accurate picture of the gross pathology taking place in the lungs during life. Amberson (3) states in his study of röntgenoscopic pathology in pulmonary tuberculosis that though the evidence is not microscopic, no other art can reveal much of the microscopic data than this form of biopsy affords, and by means of serial x ray pictures the mutations of destruction and repair may be depicted at desired intervals for months or years and the disease studied from its inception through all its pathological phases.

However, the significance of the study of röntgenographic pathology in pulmonary tuberculosis as well as the value of serial röntgenograms in correctly prognosticating such cases will be discussed fully in a subsequent contribution. The purpose of reporting and commenting on the following cases, indubitably tuberculous, as determined clinically, bacteriologically and röntgenographically, is to correct the rather rigid opinion of many a röntgenologist that one criterion of diagnosis of pulmonary tuberculosis is a certain fixity and persistence of shadow, and to bring out the fact that healing in tuberculosis does not always signify fibrosis or calcification, but that definite pulmonary tubercles may at times heal by resolution and disappear from skiagram in a comparatively short time.

Case I.—A presser, aged forty, was admitted to the sanatorium on July, 1922. His family history is irrelevant, and his past history is negative. He dated his present illness to about three months ago when he was taken ill suddenly with pain in the chest, slight pyrexia, cough and expectoration with frequently blood streaked sputum. He was confined to bed for about six weeks and began to recuperate gradually. His sputum was positive for tubercle bacilli on several examinations.

Physical examination of the chest on admission disclosed an extensive lesion in the entire left lung as well as in the upper lobe of the right lung. Röntgenographic examination at the same time showed bilateral dense infiltration of apices and first and second spaces, and moderately dense discrete infiltration throughout the major part of left lower lobe (Fig. 1). The patient did remarkably well under sanatorium treatment, his cough and expectoration subsided gradually and left him entirely after six months, he was apyretic all the time and gained in weight and strength persistently. His sputum became negative for tubercle bacilli about two months after admission, neither could the antiformin test of the sputum reveal any tubercle bacilli.

Physical examination of chest eight months after admission could disclose no adventitious sounds, except doubtful dry râles at the right apex. Röntgenoscopic examination showed marked clearing throughout, only slight haziness at right apex, and accentuation of lung markings. A radiogram taken

*From the Montefiore Hospital Bedford Sanatorium for Incipient Tuberculosis.

FIG. 1. FIG. 2

FIG. 1.—(Case I). Bilateral dense infiltration of upper lobes, and discrete infiltration throughout left lower lobe.

FIG. 2.—(Case I). Appearance one year later. Complete clearing of lesions, with only slight accentuation of lung markings.

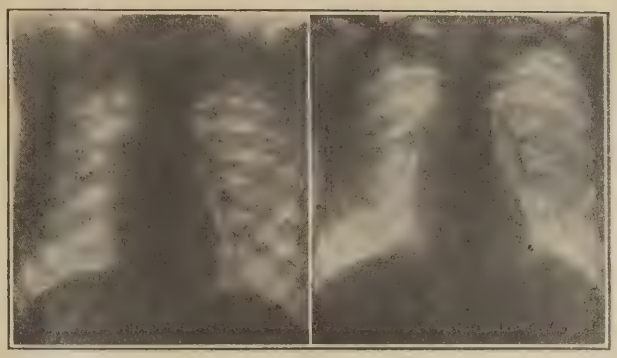

FIG. 3 FIG. 4

FIG. 3.—(Case II). Marked miliary stipplings of both lungs, the tubercles being more studded in the left middle lung field.

FIG. 4.—(Case II). Appearance two years later. Perfectly clear lung fields, only the hilum shadows appear increased with radiations in all directions.

a year later showed complete clearing of the old lesion, with only slight accentuation of lung markings (Fig. 2). Patient was symptomless all the time and attended to his work as usual.

CASE II.—A young man of twenty, admitted to the sanatorium October, 1922, with moderate pyrexia (100-100.6°), pain in chest, cough, expectoration and dyspnea. He gave a history of hemoptysis about three months prior to admission, after which high fever developed ranging from 101° to 103° which lasted about five weeks and began to subside gradually.

Physical examination of his chest on admission disclosed an extensive lesion in both upper lobes, more marked on right side, with also feeble breathing and moist râles at the right basal region.

The x ray plate (Fig. 3) taken on admission revealed marked miliary stipplings of both lungs, the tubercles being more studded in left middle lung field.

He did well under sanatorium treatment, his dyspnea disappeared, his cough and expectoration gradually diminished, and he gained in weight and strength. His sputum became negative for tubercle bacilli. Physical examination of his chest at this time showed practically no changes. A radiograph of his lungs taken at this time showed definite evidence of clearing of the collateral inflammation and the tubercles appeared more discrete.

Serial röntgenograms taken quite frequently showed the gradual disappearance and fading out of the tubercles from the plates; definite evidence of resolution. Fig. 4, an x ray plate taken about two years after the first one (Fig. 3), shows perfectly clear lung fields; only the hilum shadow appears increased with radiation into all directions.

CASE III.—An orderly, aged twenty-six, was working in the Bedford Sanatorium, but on account of fever, cough and expectoration had to give up work, and was put to bed. He gave a history of being subject to frequent colds and having a tendency to slight fever on exertion since 1915.

Physical examination at this time (March, 1919) disclosed a moderately advanced lesion of middle and upper lobes of right lung. His sputum was positive for tubercle bacilli. An x ray plate of his chest (Fig. 5) shows a considerable almost homogeneous density on a level with the second and fourth

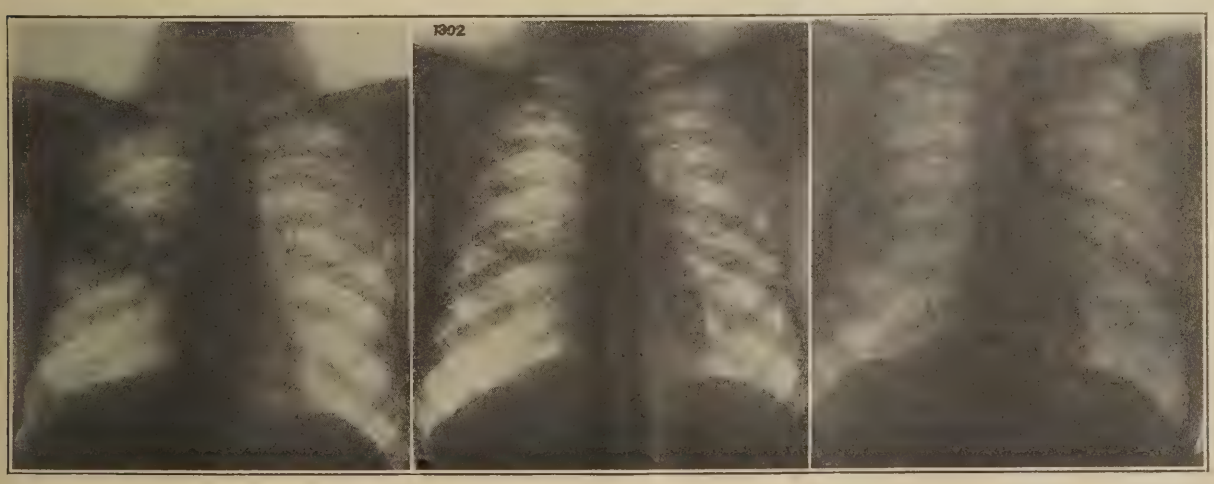

FIG. 5 FIG. 6 FIG. 7

FIG. 5.—(Case III). A considerable almost homogeneous dense shadow on level with second and fourth interspace of right hemothorax, a cavity about an inch in diameter at level of third rib near root.

FIG. 6.—(Case III). Appearance of lungs six months after initiation of pneumothorax. All the lobes of the right lung are seen partially collapsed.

FIG. 7.—(Case III). Three months after termination of pneumothorax therapy. The dense shadow seen in Fig. 5 has disappeared entirely leaving clear lungs, only in place of the cavity there is seen a small contracted scar.

interspaces of right hemothorax. A cavity about an inch in diameter is seen at level of third rib near root. There are also small scattered infiltrations at upper portion of lower lobe. The left lung shows increased root changes with radiations into all directions.

On account of persistence of symptoms and because of frequent small hemoptysis pneumothorax was induced into the right pleural cavity on April, 1919. His temperature began to fall, the general malaise disappeared, cough and expectoration diminished gradually, no blood streaks were seen in his sputum, and it became negative for tubercle bacilli. Patient did well under the treatment, and gained in weight and strength continually.

A röntgenogram (Fig. 6) taken on September, 1919, shows an effective right pneumothorax occupying the outer part of pleural cavity from apex to base. The individual lobes are clearly seen, the middle lobe being more collapsed than the other two which expand fairly well with each inspiratory movement.

Patient improved remarkably, became entirely symptomless, and returned to his work in about a year and a half. Ever since he has been working eight hours a day without any untoward results. Pneumothorax treatment was discontinued on February, 1923.

Physical examination of the chest about three months after the termination of the pneumothorax therapy revealed no adventitious sounds. Neither röntgenoscopy nor röntgenography showed any evidence of pneumothorax (Fig. 7). The dense shadow of the middle lobe has disappeared, leaving the lung entirely clear, only in place of the cavity there is seen a small contracted scar. There is no distortion of mediastinal structures, and both diaphragms function well.

COMMENT

All these cases gave a typical tuberculous symptomatology, exhibited definite physical findings of pulmonary tuberculosis, the bacteriological examinations of their sputum revealed tubercle bacilli for a long time, and they pursued a more or less stormy clinical course, but their pulmonary röntgenograms on admission differed widely in degree on involvement of the lungs, distribution of lesion, and mode of arrangement of these pathological changes. One showed dense infiltration of both upper lobes with discrete tubercles of left lower lobe, another exhibited evidence of miliary infiltration throughout both lungs, and a third disclosed caseation and cavitation of middle lobe and upper portion of basal lobe of right lung. What is more important, however, is the fact that all the lung skiagrams of these cases taken after the abatement of their subjective symptoms and the disappearance of the physical signs revealed no pulmonary pathology whatsoever, except increased lung markings,—a condition found in many nontuberculous cases. There occurred a complete resolution and disappearance of the previous tuberculous lesions.

All tuberculous cases who become clinically inactive and stop discharging tubercle bacilli in their sputum are known to the clinician as arrested cases; i. e., cases which have definite anatomical tuberculosis whose clinical activity has become arrested and has been rendered symptomless. Pathologically this means that the necrotic, caseous or infiltrative areas of the lung became fibrosed or calcified. Röntgenographically this is represented either by a homogenous clouding in a previously mottled area, or as a dense patch or even total opacity, if a pachypleuritis coexists, with retraction and distortion of mediastinal structures.

That this is the usual behavior of healed tuberculosis is almost axiomatic, but those who have done repeated physical and radioscopic examinations of tuberculous patients in sanatoria get "surprises" not infrequently; the shadow instead of becoming more dense and conspicuous, is gradually fading out of the x ray picture and may disappear entirely.

Furthermore, not always does the entire lung clear up, but while one patch may become persistently denser—indicative of fibrosis taking place, another density at the same time and in the same lung is diminishing gradually and finally disappears entirely from the radiograph. Whether this is due to a local immunity of the tissue or to a general reaction which brings about resolution instead of fibrosis can only be conjectured. Suffice it to state, however, that resolution in pulmonary tuberculosis does take place occasionally and Case I. brings it out clearly. There was a massive confluent tuberculization of both upper lobes with discrete tubercles throughout the left lung, and they all disappeared within a year or so leaving no trace of themselves, at least as far as we can determine röntgenographically.

The röntgenographic study of the case of miliary pulmonary tuberculosis is of marked clinical interest. The gravity of miliary tuberculosis is too well known by every clinician, and it almost always means death. However, recently a type of chronic miliary pulmonary tuberculosis has been described by Bierman (4), Stivelman and Hennell (5), where the disease ran a chronic course, and radiographically they found that the miliary tubercles went through all the gamut of destruction and repair by fibrosis or calcification. Krause (1) mentions a case of a woman who became acutely ill and an x ray examination brought to light miliary stippling of the lung. The woman recovered and with convalescence all shadows of pulmonary miliary involvement disappeared. If serial röntgenography were practised more frequently and persistently, cases of complete recovery from miliary pulmonary tuberculosis with resolution and disappearance of the tubercles would probably cease to be a medical rarity.

CASE III, where the patient was treated with artificial pneumothorax for about four years, deserves particular attention because it might throw definite light on the mechanism of resolution and clearing. In my work, The Classification of Artificial Pneumothoraces and Their Corresponding Clinical Value (6), I pointed out that in properly selected cases of early pulmonary tuberculosis treated by artificial pneumothorax of the expansile type, the patients may eventually recover with complete anatomical and physiological recovery of the lung. Case III is a striking example of such a recovery, as it is disclosed by the röntgenograms taken prior to the induction of pneumothorax, during the course of the treatment and after the completion of the treatment. A comparison of the x ray plates in Figs. 5 and 7

shows distinctly that the massive infiltration of the middle and lower lobes has cleared up and disappeared entirely. Of course, in place of the small cavity noticed on Fig. 5 one can see a narrow scar on Fig. 7, as we would naturally expect that the only way for a cavity to heal is by fibrosis and scarring. In this case the pneumothorax promoted healing by approximating the walls of the cavity, and served the same purpose as the sutures of a surgical wound, i. e., brought about a more rapid healing by primary intention. But the outstanding feature of this case is the resolution and complete disappearance of the massive caseous areas, at least macroscopically as far as we can detect by x rays.

It is not the purpose of this article to explain how resolution is brought about in pulmonary tuberculosis, but without going into details of the mode of production of tubercle antibodies whose exact nature is yet little understood, one could theorize that at the time of initiation of pneumothorax there might have existed an equilibrium between the toxic elements and their antibodies. By introducing gas into the pleural cavity and collapsing the lung we diminish the diseased area, squeeze out large masses of caseous material which is being expectorated, and with it we naturally eliminate a large amount of toxins. It is this elimination of toxins that brings about the immediate amelioration of symptoms to the patient, as evidenced by the fall in temperature, disappearance of general malaise, improved appetite, etc. But while the toxic elements are greatly diminished, the number of the antibodies that have already been formed against these toxins, remain the same as before, and consequently outbalance greatly the remaining toxins. Is it not possible that this overabundance of antibodies prevents a further proliferative cellular reaction in the lungs, but instead brings about resolution? This theory is inadequate in explaining resolution in cases of pulmonary tuberculosis not treated with pneumothorax, unless we hypothesize further that even in those cases an overabundance of antibodies was being formed in some way or other. No doubt more than one factor plays its rôle in the process of resolution; the character of the infecting bacillus and its manner of infecting, the native and acquired resistance of the host, the local and general immunity as well as the status and condition of host at time of infection—all these forces help to shape the final result.

Of course, it is for the experimentalist to furnish the true clue and explanation of the phenomenon of resolution in tuberculosis, but the impression is gained that it is in the exudative type of pulmonary tuberculosis, i. e., where the inflammatory features predominate over the proliferative ones that resolution may take place. Gardner (2) sums up the process of resolution in experimental pulmonary tuberculosis as follows: "The bacilli are killed by the body fluids, the caseous matter is invaded and removed by mononuclear and polynuclear cells; and the proliferated cell masses at the periphery are absorbed even as granulation tissue is absorbed after any other infectious process," but whether resolution can take place also in human pulmonary tuberculosis he is not ready to state. Krause, however, is of the opinion that resolution may go on irrespective of high or low invasiveness of germ.

There is no doubt that closer observation of pulmonary tubercles would prove that they are wiped out completely in many more instances than we are now accustomed to think likely. Of course, we speak here of the gross visible change that can be detected röntgenographically, but it is not improbable that there remains a microscopic record in such diseased tissue. Gardner found that the only signs of the previous tubercles were aggregations of lymphoid masses, but these later failed to infect guineapigs when injected subcutaneously. Miller (7) found that the human lung of the adult contains much more lymphoid tissue than that of the child. Is it not possible that this increased intrapulmonary lymphoid tissue is a remainder of previous tuberculous infection which subsided without leaving any visible traces of its former activity?

Unfortunately we cannot yet make a prognosis from one x ray plate as to the outcome of the disease, just as it is impossible in most instances to tell from one röntgenogram whether or not the disease is active or quiescent. Serial röntgenography should be practised more frequently as it is the only reliable method by means of which we can study the mutations of pulmonary shadows during life. It does bring out the fact clearly that fixity and persistence of the x ray shadow is not a necessary criterion for pulmonary tuberculosis, and that definite tubercles may at times, instead of becoming sclerosed or calcified, undergo resolution and disappear from the tissue without leaving any macroscopic trace that could be determined by x rays.

SUMMARY AND CONCLUSIONS

1. The pathological doctrine that healing of the lesions induced by the tubercle bacillus always signifies sclerosis or calcification ought to be revised somewhat; in a small number of such cases at least healing had been noticed to take place by resolution.

2. Cases of pulmonary tuberculosis are reported and a number of their serial röntgenograms are presented to demonstrate the fact that definite tuberculous shadows may fade out gradually and disappear entirely from the x ray plates.

3. The clearing and disappearance of tuberculous lesions may take place in miliary tuberculosis as well as in other types of pulmonary tuberculosis. Physical examination is of little value in detecting such changes, only by repeated röntgenographic observations can a correct prognosis be made.

4. These facts do not substantiate the opinion held by many röntgenologists that one criterion of diagnosis of tuberculosis is a certain fixity and persistence of shadow; it is the author's belief that a more systematic serial röntgenographic study of pulmonary tuberculosis would disclose a much larger percentage of instances of complete resolution, clearing and disappearance of tubercles.

Neuropsychiatry in Tuberculosis

A Survey of Two Hundred Patients

B. J. WEIGEL, M.D.

Albuquerque Sanatorium, New Mexico

Experience has shown that in chronic organic disease, functional nervous disorders bear a definite relation to the progress of the disease and in a large number of cases probably spell the difference between attaining a cure and terminating the patient's life. Functional nervous disease occupies a position today so important that we cannot ignore its relation to a disease as chronic as tuberculosis. Patients who present themselves for treatment complaining of being nervous and showing any of the earmarks of a definite neurosis, certainly invite our attention to a matter vital to their welfare. The psychiatrist for many years past has been able to demonstrate repeatedly that frank neurotics suffering from organic disease symptoms have been relieved and organic conditions cured in the course of and with the aid of psychotherapy. This has led to a study of the relation between organic and functional ailments. The abnormal psychological mechanisms observed in a large number of tuberculous patients led me to study them with a view of determining the frequency with which these conditions are met and what influence they have on the progress of the disease.

It might be stated here that a great number of psychoneurotics going through the hands of the tuberculosis specialists are not suffering from tuberculosis. They present themselves with symptoms resembling tuberculosis, but prove eventually to be entirely free from clinical tuberculosis. The phthisiophobe, on close study, often proves to be a hysteric, a hypochondriac, a psychasthenic, or a psychopathic personality, seeking relief or refuge behind this often convenient smoke screen. The neurasthenic, the hysteric, the mild precox, or the person suffering from an anxiety neurosis can present symptoms characteristic of tuberculosis, such as loss of weight, weakness, low grade temperature, vague gastrointestinal disturbances. If he gives a history of familial tuberculosis, he at once falls under strong suspicion. In addition, the chest may reveal some changes due either to an old fibrotic lesion or an acute bronchial condition and therefore present a picture which resembles incipient phthisis so closely that only careful study can differentiate. Our experience leads us to believe that many of the patients complaining of symptoms which might be considered as due to tuberculosis are either frank neurotics or individuals suffering from endocrine disorders. No doubt some of these are admitted to sanatoria for tuberculosis and treated as tuberculous with good results. One can readily see that in institutions of this kind where no member of the staff has had psychiatric training and differentiation between functional nervous disease and clinical tuberculosis is not made, the statistics as to improvements, arrests, etc., would be incorrect and indicate an efficacy in the treatment of tuberculosis which does not in reality exist.

However, the damage done in so many of these patients designated as tuberculous is that the horror of tuberculosis and the thought that he is suffering from it, constitutes a psychic trauma to the psychoneurotic and fixates so many symptoms that later psychiatric treatment becomes most difficult. This is the type of patient who will wander from one consultation room to another seeking confirmation of the diagnosis and thereby fixating the neurosis more and more. In some cases it is a question if an individual of this type and in these circumstances, originally free from clinical tuberculosis, does not eventually break down with active disease as a result of his neurosis. The cause of tuberculosis being somewhat regarded as that vague and indefinite thing "lowered resistance" certainly leaves room to suppose that an individual whose organic function is impaired through psychopathology is liable to infectious disease and that tuberculosis can make its appearance as the result of this. We meet patients in whom a neurosis has existed since childhood and all their reactions have led towards chronic invalidism. Minor organic disease having made its appearance and having been enlarged upon, they came to regard themselves as being "delicate," having "weak lungs," "lowered resistance" and have expected to break down with some serious disease. (These people seem to have a morbid satisfaction that something has come to pass for which they have waited many years.)

The necessary restraint and careful living imposed upon the tuberculous in all stages no doubt tends to bring about a chronic invalid reaction which borders on, if not actually constitutes, a neurosis. For the purpose of this study, however, that condition has been left out unless it was part of the symptom picture of the psychopathology. The mere fact that a patient at times complains of nervousness, sleeplessness, palpitation, etc., does not, of course, constitute a neurosis. It is only when these symptoms predominate the patient's reactions and cut into his personality, forming a distinct handicap, that they must be taken into consideration. Even though months and years spent in bed is an abnormal environment when compared to healthy pursuits, there is such a thing as an individual making an adjustment to this environment and keeping the personality intact. The dissatisfied chronic kicker, who is constantly beset with fears, worries and morbid ruminations certainly stands out from the normal. He it is that needs investigation and treatment which may not always conform to the accepted routine. It is this type of individual who may have to be gotten out of bed and allowed some exercise when his physical condition would contraindicate such a procedure. This cannot be and is not always practised in the larger institutions on account of the effect on the general discipline, but the smaller, and especially private institutions are not modeling themselves along lines of rigid systems but are studying their patients' individual requirements and treating them accordingly.

By this we do not mean that because an individual is neurotic he should be gotten out of bed and allowed to follow his inclinations. His condition must be carefully studied, psychotherapy instituted and his reactions guided as much as possible into normal channels.

NERVOUS MANIFESTATIONS

In a number of patients, weakness, or rather exhaustion, is a predominating symptom, and even though their tuberculosis is quiescent or arrested, they stick to their beds. An order to exercise is met with stubborn resistance and they remain in bed indefinitely. The greatest and by far the most common factor met in our series is the opposite. They have an incessant urge to be up and about and are dissatisfied with their surroundings. They are tired of staying in bed. They have heard of someone who was much sicker than they are who did not stay in bed and is now a "cure." The old idea of exercising regardless of temperature and pulse suits them and they demand to be treated along those lines. They have read all they could find on tuberculosis and unless the physician agrees with their ideas of diet, medication, etc., he does not know what he is doing and they desire to make a change. This is also accompanied by the fear that staying in bed will bring on weakness, poor circulation, sleeplessness, loss of appetite, and a myriad of other symptoms. Analysis in these individuals reveals the usual sex complexes. Impotence, real and imaginary, is the underlying factor in the majority of instances.

These manifestations have been roughly classified as restlessness for the purpose of this paper. These people certainly require the most intensive course of suggestion, persuasion and reeducation. Often tuberculous patients change climate constantly, not because they are really doing so badly in one, but because their personality is inadequate at one place, and they always entertain the hope that some other resort town might measure up. Patients of this type will complain of all the disagreeable factors—real and imaginary—of the other town and the other institution. They constantly change physicians and have usually exhausted the gamut of quack remedies always so prevalent for the cure of tuberculosis. They are certainly handicapped by their neuroses and regardless of the most skillful medical measures directed towards the disease, they frequently do not get along and lose the fight against odds, already large, for the most sane of individuals.

In this study an attempt has been made to classify as neurotic only those persons who manifest the major symptoms of a distinct psychoneurosis to the extent that it constitutes a handicap in treating the tuberculosis and interferes with the patient's welfare. As pointed out above, there is probably no patient suffering from a disease as long drawn out as tuberculosis who does not at times manifest symptoms bordering on the abnormal as far as his psychic reactions are concerned. In the normal individual, these symptoms are easily relieved by explanation and interpretation. The psychoneurotic, however, does not take to these explanations and oftentimes harm is done by trying to show him the error of his reasoning by being concise and brief. It requires a great deal of time and effort on the part of the physician to convince these patients that a neurosis may exist in addition to organic disease and that abnormal mental reactions influence organic function.

The series of patients here studied was taken in the order in which they occurred in the files of our institution. They represent, we believe, a cross section of patients as they are admitted for treatment in the average sanatorium, at least in the West. There is reason to suppose that the health resort often attracts a type of individuals somewhat afflicted with the *Wanderlust* and that he is seeking new scenes rather than actually expecting benefit from a different climate. This type of individual is, of course, not normal and no doubt we have him occurring in this series to the extent that our total number of psychoneurotics is slightly raised by his presence.

AGE, DURATION, AND RACE

In this series, the average age of the patients was thirty years and seven months. Duration of the disease when they came under our observation varied from one month to twenty-six years, with an average duration of four years, six and a half months. There were one hundred and sixty native born Americans, eight Germans, eight Jews, seven Swedes, three Irish, two Greeks, two Indians, two Bohemians, one Swiss, one Austrian, two Canadians, one English, one Scotch, one Syrian and one Norwegian.

ORGANIC FACTORS

Other organic factors encountered in these two hundred patients showed ten to have chronic malaria, eight syphilis uncomplicated, one syphilis with gonorrhea, one syphilis with diabetes, and one syphilis with aneurysm, which was the causative factor in his death. Three had mitral stenosis, one a massive secondary mixed infection, one a nontuberculous pyelitis and one a colitis of rather severe degree. Twenty goitres were present and three patients showed pronounced pituitary involvement.

PSYCHONEUROSES AND PSYCHOSES

Of the two hundred patients studied, ninety-four, or forty-seven per cent., were suffering from a definite psychoneurosis or psychosis. Fifty-two or fifty-five and five tenths per cent., of these ninety-four had hysteria; twenty-six, or twenty-seven and three tenths per cent., neurasthenia; five, or five and three tenths per cent., were precoxes; five, or five and three tenths per cent. were constitutional psychopathic states; two, or two and one tenth per cent., were hypochondriacs; one, or one and one tenth per cent., manic depressive insanity of the depressed type; one, or one and one tenth per cent., psychasthenic; two, or two and one tenth per cent., had general paresis; one, or one and one tenth per cent., manifested presenility. In the hysterics, five were complicated with large anxiety elements and one with marked inferiority. Two of the neurasthenics possessed anxiety elements. Two of the five patients with dementia precox were of the hebephrenic type, one was a simple precox and two showed precox personalities.

SYMPTOMS

The restlessness described above was the prominent symptom in sixty-three, or sixty-eight and eight tenths per cent., of the patients showing neuroses.

Insomnia, the next most frequent symptom, occurred in fifty, or fifty-three and two tenths per cent. Vague gastrointestinal symptoms which could not be explained on an organic basis occurred in twenty-five, or twenty-six and six tenths per cent. Anxiety to the extent that it constituted a neurotic symptom occurred in fifteen, or fifteen and nine tenths per cent. Instability, defined as an unstable personality with emotional upsets, inadequate personality, and states bordering on the hysterical, was present in thirteen, or thirteen and eight tenths per cent. Weakness, which was not due to organic disease or not adequately explained by it, was present in eight, or eight and five tenths per cent. Worry occurred in twelve, or twelve and eight tenths per cent. Palpitation, for which there was no explanation, other than neurotic, was a prominent symptom in five of the patients; in three apprehension was a big factor; irritability in three; waywardness in three; mental depression in seven; pathological fear in three; stuttering was present in three; two were mildly deluded; very marked inferiority was present in one; aboulia in two; asthma on an entirely neurotic basis was present in one; pathological forgetfulness in one; exhaustion in one; ideas of grandeur in one.

TUBERCULOSIS CLASSIFICATION

The one hundred and six normal patients came under the following classification: Far advanced, fifty-four, or fifty-one and four tenths per cent.; moderately advanced, thirty-two, or thirty and four tenths per cent.; incipient, nineteen, or eighteen per cent., and one had a tuberculous hip. Of the psychiatric patients, fifty-six, or fifty-nine and two tenths per cent., were far advanced; twenty-two, or twenty-three and four tenths per cent., moderately advanced; sixteen, or seventeen per cent., incipient. Roughly, the stage of the disease was the same so that the far advanced tuberculous is not necessarily more liable to manifest a psychoneurosis. When we consider that the average duration of the disease in the two hundred patients was four years, six and a half months, it would lead one to suppose that on the whole the neurotics had ample time to fixate their symptoms and let them interfere with the progress.

PROGRESS OF THE PATIENTS

Of the one hundred and six normals, seventy, or sixty-six per cent., made good progress during our observation. Nineteen, or seventeen and nine tenths per cent., are known to be dead; in sixteen, or fifteen per cent., the progress was only fair; one disappeared from our observation and his fate is unknown. In the neuropsychiatric group, twenty-six, or twenty-seven and six tenths per cent., are known to be dead; twenty, or twenty-one and two tenths per cent., made good progress; twenty-eight, or twenty-nine and eight tenths per cent., made fair progress; very poor progress, besides those that died, was seen in fourteen, or fourteen and eight tenths per cent.; in six, or six and one tenth per cent, it is very questionable whether they are alive. Of the forty-seven hysterics with no concomitants, sixteen made fair progress, ten are known to be dead; nine got along well, eight, besides those that died, made very poor progress, and in two cases the fate is unknown. In the uncomplicated neurasthenic group, eight are known to be dead, six got along well, in seven the progress was fair, one did very poorly, and two are lost track of with questionable outcome. In hysteria with concomitants—one in the anxiety group died, two got along well, one fairly well, and one very poorly. The patient with infantilism and hysteria did very well. The hysteric with very marked inferiority did badly and her fate is not known, but she is probably dead. In the precox group, the three fully developed precoxes died, one being a suicide. In the constitutional psychopathic state group, two died, one's progress was good, one fairly good, and one very poor. The two hypochondriacs progressed fairly well. The two with general paresis did very poorly. The one in the presenile state we have lost track of and her outcome is very doubtful. The patient with manic depression insanity died. The psychosthenic progressed well.

PSYCHOTHERAPY

Psychotherapy was employed in forty-eight of the patients. Some of these patients were located outside of the institution and it was very difficult to treat them satisfactorily. A complicating factor so often met in this series was the presence of members of the families accompanying the patients and being in constant attendance upon them. This handicaps one in attempting to treat by isolation, which is, of course, good practice in these cases. Nevertheless, markedly favorable results were obtained in at least twenty-seven of these patients. This is considered well worth while and leads one to believe that intensive psychotherapy in proper surroundings is a great aid in treating the tuberculous.

This paper is a plea for men in tuberculosis sanatoria to familarize themselves with neuropsychiatry and undertake the study of the psychologic makeup of every patient. The successful men in practice many times possess keen insight into the patient's psychobiological makeup and practice psychotherapy instinctively. This probably constitutes the greatest weapon outside of specific therapy in the physician's armamentarium when he is confronted with organic disease. However, not all are blessed with this gift but training along neuropsychiatric lines will fill this long felt need.

CONCLUSIONS

1. Functional nervous disease occurs with great frequency among the tuberculous.

2. The disturbances in bodily function by a neuropsychiatric state can no doubt constitute a predisposing factor in tuberculosis.

3. Psychoneurotics are sometimes wrongly diagnosed as tuberculous and find their way into institutions for the treatment of tuberculosis.

4. It is a question as to just how much of a rôle these patients play in statistics reported from institutions where neuropsychiatric diseases are not recognized.

5. Neuropsychiatric diagnoses in patients with tuberculosis and proper psychiatric treatment are a definite help in the treatment of their tuberculosis.

6. The psychoneurotic has a definitely worse prognosis for his tuberculosis than the individual with approximately normal personality.

Historical Medicine

A Minor De Quincey

LOUIS J. BRAGMAN, M.D.

Syracuse, N. Y.

INTRODUCTION

In 1837, sixteen years after the master essayist, De Quincey, had produced the *Confessions of an English Opium Eater,* Fitz Hugh Ludlow was born in Poughkeepsie, N. Y. Upon graduation from the Union College at Schenectady at nineteen, he immediately entered into the sphere of letters. *The Hasheesh Eater,* subtitled *Passages from the Life of a Pythagorean,* written while he was a student and published in 1857 in Putnam's magazine, promptly earned for him a wide recognition.

During the following years he held various literary positions, among them that of editor of *Vanity Fair* from 1858 to 1860, correspondent for two successive years with the *New York World,* the *Evening Post* and the *Commercial Advertiser,* and, for a time, dramatic, musical and art critic for the *Home Journal.* He also wrote steadily for *Harper's Monthly,* chiefly short stories, and was one of the leading contributors to the *Northern Lights,* a Boston periodical. "What Shall They Do To Be Saved?" appeared in *Harper's Monthly* in 1867 and "The Opium Habit" in 1868. Two years later he died in Geneva, Switzerland, a victim of the selfsame habit he so strenuously inveighed against.

The writings of Ludlow show him to have possessed a keen sense of humor, a remarkable insight into character, and a very refined feeling and taste. But apart from the fact that on at least three occasions he not merely touched upon but delved deeply into the vagaries and vicissitudes of the habit forming drugs, opium and hasheesh, little is known of his associations with the drugs themselves or how they affected his life and career. The following summary of his impassioned indictment against the treacherous poppy seed may perhaps shed some light on this matter.

"WHAT SHALL THEY DO TO BE SAVED?"

"God seems to help a man in getting out of every difficulty but opium. There you have to CLAW *your way out over redhot coals on your hands and knees and drag yourself by main strength through the burning dungeon bars."*

In this intense and vivid discourse are presented, in a masterful fashion, "a few considerations regarding the action of opium on the human system while living, and the peculiar methods by which the drug encompasses its death." The author assumes the rôle of a physician, pretending that he is treating a friend who is an extreme addict. As he sketches the rapid stages in the downfall of the pitiful victim, he makes forceful and elucidating comments on the various features of the pernicious habit.

One is inclined, however, to the suspicion that Ludlow has here recorded his own personal adventures with the drug that he calls vindictively "a corrosion and paralysis of all the noblest forms of life." The impassioned tone and pathetic strain that resound throughout, the vigorous and indisputably realistic descriptions that bespeak first hand knowledge, capped with the fact above mentioned that he died at thirty-three of the opium habit, afford ample ground for such an assumption. For it is not an uncommon occurrence for men of letters (and Ludlow was a capable and natural writer) to discuss the results of their intimate tamperings with the imagination stirring but disaster wreaking drug.

"There are certain men," he begins, "to whom opium is as fire to tow." His friend was the case in point. His first contact with the drug was a cursory one early in life. But it was not until he became afflicted with an attack of inflammation of the cornea that his indulgence began to any intensity. A doctor whom he had consulted eight years previously had prescribed, in addition to a local application to the eye, internal doses of "M'Munn's elixir" to quell the excruciating pain. This remedy was a prevailing quack preparation, allied chemically to tincture of laudanum.

When he emerged from the dark room at the end of a month and his bandages were removed, he had consumed twenty ounces of the elixir. He then began taking it at short intervals, totaling fifty drops daily, but within a month this was of necessity increased to an ounce a day. When the eye was completely healed he stopped the use of the anodyne—but not for long. For "he had not forgotten the sweet dissolving views at midnight, the great achievements at noonday, the heavenly sense of selfreliance which dare go anywhere, say anything, attempt anything in the world. He had not forgotten the nonchalance under slight, the serenity in pain, the apathy to sorrow, which for one month set him calm as Buddha in the temple splendors of his darkened room. He had not forgotten that the only perfect peace he had ever experienced was there, and he remembered that peace as something which seemed to blend all the assuaged passion and confirmed dignity of old age with that energy of high emprise which thrills the nerves of manhood."

And so at the age of forty he found himself an habitué of eight years' standing. Whenever the world went wrong with him he resorted to M'Munn's. It soon became imperative that he increase the dose to keep his appetite satisfied. Yet even then the elixir finally proved inefficient, so he changed to laudanum, "which contains the full native vigor of the drug unmodified." But this, as well as gum opium, opium pills and opium powder, which he likewise tasted, nauseated him, and he was thus ultimately "driven to that form of exhibi-

tion which sooner or later naturally strikes every opium eater as the most portable, energetic, and instantaneous—morphine or one of its salts."

With time his daily consumption ranged from twelve to twenty grains, one half immediately after rising, the rest just about sundown. Physically at this period his body was in no way impaired, but he came to the conclusion that he "*must* emancipate himself, because opium eating was a horrible mental bondage."

The pleasures and dubious joys of the addiction were waning. The victim found that "the image graving and project building characteristic of opium, which comes on with a sense of general radiation from the epigastrium about a quarter of an hour after the dose, had not yet so entirely disappeared from its effect on him, as it does at a later stage of the indulgence. But instead of being an instigation to the delightful reveries which ensued on his earlier doses, this peculiarity was now as an executioner's knout in the hands of remorse. He was daily and nightly haunted by plans and pictures whose feverish unreal beauty he remembered having seen through a hundred times. Those Fata Morgana plans, should he again waste on them the efforts of construction? The result had been a chaos of ineffectual days. Those pictures, why were they brought to mock him? Were they not horrible impossibilities? Were they not, through the paralysis of his executive faculties, mere startling likenesses of disappointment? In his opium dreams he had seen his own ships on the sea; commerce bustling in his warehouse; money overflowing in his bank. . . . How pleasurably he had once perceived all these possible joys and powers! How undeludedly he now saw their improbable execution!"

But alas for good intentions! The physical hold of the drug by this time was too strong—and "the spiritual thralldom was his hourly misery." Under the hand of the doctor the doses were gradually reduced, until he was taking only one half a grain a day. But nocturnal paroxysms necessitated the restoration of the original amount, for "when a man has used opium for a long time, the condition of the brain supervening on his deprivation of the drug for a period of twenty-four hours is such as very frequently to render him suicidal."

The power of the will and grim determination were handicapped from the start by the strenuous hold of the drug on the mind. It had long passed the stage of "I can" and "I will." And this is what Ludlow says on the matter of the blame: "Whatever may have been the patient's responsibility in *beginning* the use of narcotics or stimulants (and I usually find, in the case of opium eaters, that its degree has been very small, indeed, therapeutic use often fixing the habit before the patient has convalesced far enough even to know what he is taking), habituation invariably tends to reduce the man to the *automatic* plane, in which the will returns wholly to the tutelage of sensation and emotion, as it was in infancy; while all the intellectual, save memory, and the most noble and imperishable among the moral faculties may survive this disorganization for years, standing erect above the remainder of a personality defrauded of its completion to show what a great and beautiful house might have been built on such strong and shapely pillars."

The denial of the drug brought on an agony "which took his actions out of voluntary control, eclipsing the higher ideals and heroisms of his imagination at once, and reducing him to that automatic plane in which the nervous system issues and enforces only those edicts which are counseled by pure animal selfpreservation." The only recourse left was to send him to a water cure where absolute deprivation could be maintained. He was accordingly starved of his Nepenthe for ninety days during which time he knew no normal sleep. He fell into a semiconscious state and for the last fifty days sat constantly bolt upright in bed.

At the end of the treatment he was almost prostrate, in intense agony, and mentally confused. The prognosis was very gloomy, so the baneful drug was restored to him, for further struggle meant sure death. The patient's final injunction was heartrending: "It is almost like Dives asking for a messenger to his brethren; but tell them, tell *all young men* what it is, 'that they come not into this torment.'"

Is there then no hope? Must the note be always pessimistic? Not always, for "over the opium eater's coffin, at least, thank God! a wife and a sister can stop weeping and say, 'He's free.'"

The course on the road upward, Ludlow says further in discussing the attempted cure, is very perilous. "The records of fatal lesion, mechanical childbirth, cancerous afflictions, the stake itself, contain no greater tortures than a confirmed opium eater experiences in getting free." The recovery is to take weeks and months; "who is sufficient for this long, *long* pull?"

Twenty-four hours after the deprivation, the torments begin. First there is a peculiar "corded and tympanic tightness about the epigastrium . . . then a feverish condition of the brain which sometimes amounts to absolute phantasia." Following this occur periods of increasing excitement marked off by heavy sleep, which after each interval "grows fuller of tremendous dreams, and breaks up with a more intensely irritable waking." In forty-eight hours the heavy sleep disappears. "Every nerve in the entire frame now suddenly awakens with such a spasm of revivification that no parallel agony to that at this stage can be adduced." This horrible state continues for a week with neither lull nor exhaustion.

A pronounced and significant phenomenon, we are told, has now supervened. After the third day, "profuse and increasingly acrid bilious diarrhea occurs, which must not be checked if diagnosis has revealed sufficient constitutional vigor. . . . The spontaneous termination of the diarrhea will indicate that the effete matters we must remove have been eliminated." Soon after this there is a mitigation of the pain, followed by great debility.

Subjectively, the agony of the struggle is very pronounced. There is a "dull, aching sensation between the shoulders and in the region of the loins. . . . The most intense gastric irritability appears in the form of an aggravation of the tympanic tightness, corrosive acid eructations, heartburn, water-

brash, and a peculiar sensation, as painful as it is indescribable, of selfconsciousnes in the whole upper part of the digestive canal." Concomitant with the gastric sufferings, there is a neuralgic pain which spreads down the extremities from a centre between the kidneys, through the trunk, and through the "whole medullary substance of the brain, itself." Comparing the pain with that of tic douloureaux, he says that it has periods of exacerbations like the tic, but none of its continuous repose; like it, it fluctuates, but affects the entire body rather than a single area.

To heap coals on the blazing fire, there is a torturing hyperesthesia. The slightest touch hurts, the least jar aggravates, as it does a martyr to acute rheumatism. The very hair and nails feel sore, and the whole surface of the skin suffers from cold air or water "like the lips of a wound."

If bodily punishment were the entire mete, the treatment might perhaps be endured. Yet "the totality of the experience is only conceivable by adding this physical torture to a mental anguish which even the Oriental pencil of De Quincey has but feebly painted; an anguish which slays the will, yet leaves the soul conscious of its murder; which utterly blots out hope, and either paralyzes the reasoning faculties which might suggest encouragements, or deadens the emotional nature to them as thoroughly as though they were not perceived; an anguish which sometimes includes just, but always a vast amount of unjust selfreproach, which brings every failure and inconsistency, every misfortune or sin of a man's life as clearly before his face as on the day he was first mortified or degraded by it—before his face, not in one terrible dream, which is once for all over with the sunrise, but as haunting ghosts, made out by the feverish eyes of the soul, down to the minutest details of ghastliness, and never leaving the side of the rack in which he lies for a moment of dark or daylight, 'til sleep, at the end of the month, first drops out heaven on his agony."

What shall the doctor do to save them? There are several lines to follow. "When the most powerful alleviative known to medical science has bestowed its last Judas kiss which is necessary to emasculate its victim, and, sure of its prey, substitutes stabbing for blandishment, what alleviative, stronger than the strongest, shall soothe such a doom? I may give chloroform. I always do in the denouement of bad cases."

That, of course, is the ultrahumane method. The doctor might, our author tells us, speak as follows to the average case of ten years' duration:

"Sir, the chances are entirely against you, and the possession of a powerfully enduring constitution, if you have it, forms a decided offset in your favor."

He then advises immediate entrance upon the road of selfabnegation. If the case is hopeless from the start he may elaborate to this effect:

"You have either suffered a disorganization of irreproducible membranes, or you have deposited so much improper material in your tissues that your life is not consistent with the protracted pain of removing it. One by one, you have paralyzed all the excretory functions of the body. Opium, aiming at all those functions for their death, first attacked the kidneys, and with your experimental doses you experienced a slight excess of dysuria. As you went on, the same action, progressively paralytic to organic life, involved the liver. Flatulence, distress at the epigastrium, irregularity of the bowels, indicated a spasmodic performance of the liver's work which showed it to be under high nervous excitement. Your mouth became dry through a cessation of the salivary discharge. Your lachrymal duct was parched and your eye began to have an *arid* look in addition to the dullness produced by opiate contraction of the pupil.

"All this time you continued to absorb an agent which directly acts for what, by a paradox, may be called fatal conservation of the tissue. Whether through its complexly burned nitrogen, carbon or both . . . the drug has starved the fires of your whole system. . . . You have sealed up all but a single excretory passage—the pores of the skin, and when that gives out, your body shall be shut up like an entirely choked chimney.

"The condition both of your nervous system and your stomach indicate that you must always take some anodyne to avoid torture, and *your* only anodyne is opium. The rest of your life must be spent in keeping comfortable, not in being happy."

A closing plea Ludlow makes anent the insidious drug which "sings to every sense a lulling song from which it may not awake for years, but wakes a slave":

"Would to God that every young person could stand for a single hour by the victim's bedside before Life's responsibilities have become the sentinels and Habit the jailer of the Will."

Buried though they are in the dust and files of nearly seventy years, these words carry today a portentous meaning. "What Shall They Do To Be Saved?" is withal a living, a truthful, and a highly authentic document.

513 Irving Avenue.

Hippocrates and His Temple of Health.—In this century, through the labor of Dr. Rudolph Herzog of Tübingen, has been brought to light the great ruined Health Temple of Cos, where Hippocrates, the Father of Medicine, practised, Dr. Saleeby tells us in his book, *Sunlight and Health.* It was a temple to Æsculapius, son of Phœbus Apollo, god of the sun and of music and of medicine, a grouping of realms which medical men of today do not consider so widely separated as their forefathers might have done. The road from Cos to the temple was a sacred way and the priests were physicians.

This Health Temple was about two miles from the seashore and had an elevation of about three hundred and twenty feet above sea level. It was built on the slope of a range of mountains that rise from the southern coast of Cos to a height of nearly three thousand feet.

A drawing of the temple shows that its chief features were three sided, colonnaded and open stoas, or porticoes. There was evidence of an aqueduct and of great tanks or basins, doubtless used for the preliminary ceremonial ablutions of the patients.

Contributors to the Science of Medicine

Thomas Sydenham

Among English speaking medical men who have contributed to the advance of the science of medicine Thomas Sydenham occupies a conspicuous place. He was a commonsense, blunt spoken Englishman, but a genius in his way and one who observed for himself and acted upon his observations, being untrammeled by tradition. His methods were unorthodox to an extent which ran counter to the traditional dogmas of his profession to such an extent that they naturally invoked fierce and bitter attacks from his colleagues. No doubt his four years in the army and his travels and sojourn in foreign countries had largely dissipated narrow and provincial views and thus had kept his mind open and had prevented him from accepting without question all the fantastic medical theories of his time. His was an original mind and he probably did more to place British medicine on a sound footing than any other one man. Sydenham, the puritan, brought about almost a revolution in the conception and practice of medicine, while Wiseman, the royalist, his contemporary, did much for the uplifting of the art of surgery.

Thomas Sydenham was born at Wynford Eagle in Dorsetshire, towards the end of 1624, and died on December 29, 1689, in London. The average medical man knows little, as a rule, of the makers of medicine and surgery, although perhaps more is known of him who has been termed with justice the English Hippocrates, than of many of this glorious band. It is generally known, for example, that Sydenham did much to elucidate the subject of fevers, which before his time was in a state of great confusion. He was the first to give a vivid clinical description of scarlatina and his account of the form of chorea bearing his name is still regarded as a classic. Also he was largely instrumental in making general the use of Peruvian bark for agues and lastly he gave a remarkably clear and entertaining account of gout, from which he suffered himself.

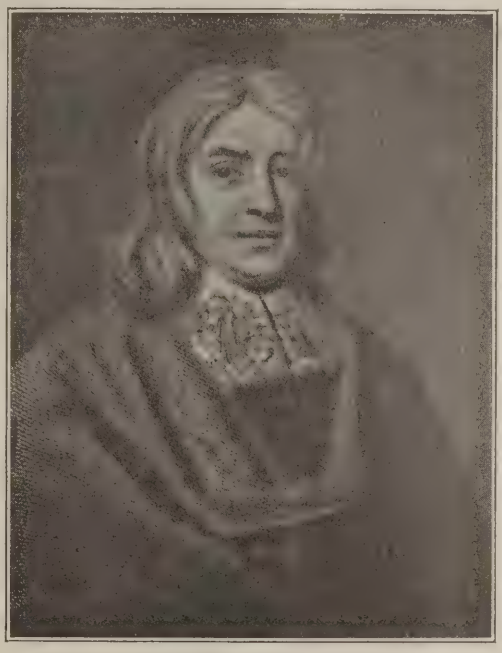
Facts regarding his early life are vague and fragmentary. It is known that he was the fifth child in a family of seven sons and three daughters. Both his father, William Sydenham, and his mother, Mary Jeffrey, belonged to old established families of importance and substance in the shire of Dorset. He was born into stirring times, as he had barely reached manhood before civil war broke out. The father, when an elderly man, served as captain in the Parliamentary Army, and was for some time a prisoner in the hands of the Royalist Army, and Thomas left his studies at Oxford to serve first as a trooper, and later as a captain in the Parliamentary Horse. In May, 1642, he had matriculated as a Fellow Commoner at Magdalen Hall, now merged into Hertford College, which was the centre of the Puritan movement in the University of Oxford. Before Sydenham matriculated, preparations for revolution had been made, and in August of that year civil war began. Sydenham's studies therefore at that time were brief. He joined the parliamentary forces and for a period of three and a half years was engaged in fierce guerilla warfare in his native county of Dorset. He was wounded in a sortie from Weymouth and in another sortie the royalist surgeon Richard Wiseman was nearly taken prisoner. In a petition to Cromwell, dated March 3, 1653, with regard to the recovery of certain moneys, Sydenham speaks of having "himself faithfully served the Parliament with the loss of much blood and thereby much disabled his body." It may be thought somewhat curious that Sydenham does not refer to his military experiences but when it is borne in mind that when he wrote Charles II was king and that he and his family had been staunch opponents this omission will be well understood.

Sydenham spent four years in war, returning to Oxford in 1646, and in 1647 entering Wadham College, he was created on April 14, 1648, a bachelor of medicine. In the same year he was elected a Fellow of All Souls' College in the place of an expelled royalist. In the next year he was appointed senior bursar of the college. Sir Christopher Wren, the great architect, was a Fellow of All Souls College at the same time. It is worthy of note that Wren, Boyle, the great scientist, and others formed some years later, the little coterie of friends in All Souls College, out of which the Royal Society for the Advancement of Science originated. In 1655 Sydenham resigned his fellowship and in the same year was married. By order of Cromwell he had obtained shortly before the money due to him and with this, the equivalent of about £2,000 at the present day, he set up practice in Westminster. At the time of the restoration of the Stuarts to the monarchy Sydenham spent a period of study at Montpellier, the celebrated French medical school. Here he is believed to have studied under Barbeyrac, a physician who had made for himself a great reputation throughout France, a man of original ideas, and of simple and successful methods of treatment. He was back at work in 1661 and in that year began his celebrated series of observations on the fevers prevalent between the years 1661 and 1675. In 1663 he was admitted Licentiate of the College of Physicians.

At that time it was illegal for anyone to practise medicine in or within some miles of London without possessing this license. During the early years of practice, the rule had been allowed to lapse for a time after the war, and in any event Sydenham had proved himself so loyal a supporter of Cromwell that it is unlikely that steps would have been taken against him. But the college now began again to assert its rights. On account of Sydenham's novel and successful methods of treatment he had many detractors and enemies and especially in the College of Physicians. However, if he had enemies he had also many warm friends. Many well known men abroad, too, adopted his views. One of Sydenham's

friends was Robert Boyle, already referred to as one of the founders of the Royal Society, and one of the greatest scientific geniuses of all time. John Locke, the well known physician, was another great friend of Sydenham. Not being a ready writer it seems that several of Sydenham's published works were written on the earnest solicitation of distinguished friends, and some of his shorter writings take the form of epistles addressed to members of the profession. It was apparently the custom of Sydenham to receive pupils into his house. Bartholomew Beale, for instance, who afterwards practised in Coventry, and whose mother, Mrs. Mary Beale, painted the portrait of Sydenham now in the building of the College of Physicians in London.

As said before, when Sydenham returned to London after his visit to Montpellier, he must have spent much of his time in the observation of fevers. His *Methodus Curandi Febres Propins Observationibus Superstructa,* of which the first edition was issued in 1666 and in the same year reprinted in Amsterdam, was his first medical publication, at the age of forty-two years. His best known and perhaps most valuable treatise or monograph is that on gout, a disease from which he suffered more or less severely from the age of thirty. In a day when bleeding, purging and sweating were the only modes of treatment recommended for gout, he used to advise his patients to reduce the number of their meals, to take a milk diet, to go to bed and to get up early and to take a moderate amount of exercise daily. Contrary to the medical theories of the time, he held that acute fevers were a protective mechanism of the body. He believed that nature was always striving to fight disease, and he advocated a return to the Hippocratic practice of watching and aiding the natural crises in disease.



THOMAS SYDENHAM

Sydenham's works, which were all written in Latin not always of the best, were brief and to the point and, as a rule, so far as treatment was concerned greatly in advance of the times. Although he was imbued with some of the old traditional superstitions of Arabian medicine, which dominated treatment at that period, on the whole he shook off the trammels of tradition and reverted as much as possible to the doctrines taught by the Greek school. Sydenham was *facile princeps* the great clinical teacher to a great extent, his treatment was governed by the results of his own observations and to a lesser extent by his own experiments. He was an extremely acute observer and the great master of expectant treatment, leaving the patient to rely on the natural powers of resistance of the body for the most part, only intervening with artificial aid when serious symptoms supervened.

It may be well believed that this expectant treatment met with great opposition at the time when Arabian therapeutics held full sway and medicine was regarded by the public as a mystery and the doctor as a kind of medicine man. This belief was deliberately fostered by the heads of the profession, who found it less trouble and more to their pecuniary advantage to let matters rest. The pioneer in any branch of endeavor is looked upon with distrust by his established brethren and the reformer is invariably considered a mischievous crank who ought to be promptly and completely suppressed. Sydenham was no exception to this general rule founded upon certain inherent human traits. As said before he was in ill odor among the self seeking of the profession, that is the majority who antagonized him and his methods by all means in their power.

Sydenham insisted upon the great underlying principles of medicine which indeed are everlasting. He was a man of foresight and of great commonsense and what he wrote concerning disease and its treatment for the most part was not for an age but for all time. Among his medical writings and observations those on the history and cure of acute diseases, on the epidemic diseases, on venereal disease and on smallpox deserve especial mention. In the treatment of lues venerea Sydenham appears to have been the originator of the idea common in later times that the cure was effected by the salivation which the administration of mercury induced and not directly by the mercury. In the treatment of phthisis Sydenham introduced into England the method of fresh air and voyages practised by the ancient Greeks and Romans and incidentally it may be that pulmonary tuberculosis must have been considerably more prevalent in England in the seventeenth century than now, as on the authority of Sydenham it is stated that two thirds of all the people who died of chronic disease perished from this cause. Apart from gout, which was the bane of Sydenham's life, from the age of thirty he appears to have had a happy domestic life. As for personal appearance, the portraits painted by Mrs. Mary Beale and Sir Peter Lely give a good idea of the man. It is to be gathered that he was of a robust, sanguine physique, with brown hair worn long without a wig, that his eyes were grey, his expression sad if not gloomy, grave but not austere and kindly though not suave or polished. His manner as befitted that of a one time puritan and roundhead trooper was, it may be imagined, blunt and forcible. Sydenham died on December 29, 1659, at his house in Pall Mall, London, and was buried in St. James' Church, Piccadilly.

The illustration is from a picture in the Hall of All Souls College, Oxford.

NATIONAL POLITICS AND HEALTH

Politically, Washington is *sui generis,* which, in the language of a certain autogenous statesman, does not mean a generous Swede. Aside from the professional statesman and that shady group which alleges to have inside information and underground prestige and whose methods would shame a case hardened racetrack tout, the city contains a large population group composed of professional uplifters who are ready to reform something and to tinker with the vitals of the ship of state at a moment's notice. These three bodies give the political atmosphere of Washington its essential bouquet, which the clerkly class and the military stratum do little to dilute. Intensely selfcentred, Washington in spirit is as far away from the rest of the country as it is possible to get and therefore political forecasts from the Capitol are almost always wrong. It was freely prophesied in the District, for example, that the bonus bill would not pass. It passed. It was the general belief that the Senate would sustain the veto. It did not. It was believed that the child labor amendment would not be passed. It was. There is only one safe guess in Washington: the opposite of the current rumor is generally correct. Conversely, the opinion in the country, unless it is an overwhelming votegetter, is not the opinion of Washington.

Consider what has happened to the long desired Department of Public Health. Time and again medical luminaries have appeared before congressional committees to give expert testimony as to the necessity of grouping under one head all of the medical, sanitary and welfare functions of the government. They were listened to with bored politeness; the altruists returned to their homes; a few paid workers remained on the job until the money gave out; the hearings were neatly embalmed in public documents; nothing happened and two or three public spirited physicians were disillusioned of a portfolio.

The philosophical say that the plan is a good one and is a part of the "check and balance" principle on which our form of government rests; that we are approaching the British system, which generally requires a generation of effort before an elemental law can be enacted; that precipitate legislation is unwise and carries undreamed of consequences in its train. All of which is platitudinous verbiage. The minute a National Department of Health can be made a campaign issue, the moment that the people want it sufficiently to go to the polls on the question, Congress will begin to sit up and take genuine notice and not until then. Minor platform planks expressing academic interest in health matters will do little to this end. Platforms are little read and soon forgotten. The presence of a lively epidemic would do more than many orators; the voice of Farmer Corntassel will be more provocative of action than that of Dr. Pillbags; above all, the people who want a National Department of Health must get together on a practical program—one in which there is less uplift and more economic wisdom. Washington is nauseated with half baked plans; Political Washington regards most of the Department of Health talk as bunk and it is doubtful if health alone can ever be made into a department. A Department of Public Welfare to replace the Department of the Interior and to include education, health, hospitalization, and pension features is more highly thought of, and had President Harding lived it was the hope of Brigadier General Sawyer that something might be accomplished along this line. Just now everything seems to wait on some one man who is strong enough to decide what is to be done and fearless enough then to go and do it. Meanwhile, we have no National Department of Public Health.

SOME ASPECTS OF THE TUBERCULOSIS PROBLEM

Tuberculosis we have with us always, and although in this country it has decreased in recent years, it remains still the most destructive disease to life and health. There is no doubt that the most effective way of fighting tuberculosis is to prevent it; not so much to prevent it from exhibiting itself, but to prevent it from developing from the early stage, when, in fact, it may be permanently checked. Environment, diet, and so on, indeed careful hygiene, generally are the most effective preventive measures; doing away with the slums of cities, housing the population in hygienic dwellings and providing healthy factories and workshops, providing nutritious food and educating each and all what to eat.

The leading authority on certain aspects of the tuberculosis question is Professor Theobald Smith, of the Edinburgh Medico-Chirurgical Society and gave an address on the subject at a joint meeting of the Edinburgh Medico-Chirugical Society and the Tuberculosis Society of Scotland. Professor Smith referred to the immunization method of grappling with the problem and pointed out to the

audience the difficulty of killing the tubercle bacillus because of the way in which it protects itself by a fatty envelope, a difficulty which Professor Dreyer of Oxford thought he had overcome, and also by causing the formation of a tubercle.

In summarizing the history of bacteriology he recalled the classical work of Koch and added that he did not think research work was so well done nowadays. Professor Smith emphasized the point that all the researches which had been done did not tell us everything, for today we may still legitimately ask the question, What are the channels of infection? In 1901 came the announcement of the distinction between the human and the bovine bacillus. The idea, though only in 1901 recognized widely, had, in fact, been adumbrated by the lecturer himself some years before, and speaking in 1908 Professor Koch publicly acknowledged that its origin was Professor Theobald Smith's paper in 1896. It should always be borne in mind that it was Professor Smith who first suggested the bovine origin of certain forms of tuberculosis. Moreover, he discovered what is now known as the phenomenon of Theobald Smith, with its important bearing on anaphylaxis.

In historical succession to the announcement of the distinction between the human and bovine bacillus came the work of the French school, which laid claim to having established the fact that ingestion of the organism in childhood was the cause of all tuberculosis. Somewhat later and even in our own day appeared the question of superinfection and its profoundly important bearing on the course of the disease.

Professor Smith explained the line of the more recent work. It was the method of making a large number of autopsies of cattle infected with tubercle. In the greatest number the disease affected the lymphatics draining the lower lobes of the lungs. This raised the interesting problem of why the upper lobes were more commonly infected in man. In the opinion of the lecturer the entire lung is infected originally, but the morbid process is suppressed in all but the upper lobes. An interesting question is raised by the predominance of lymphatic tuberculosis in cattle. Children are affected in the same way. Through economic selection all cattle are killed in what is their infancy, and thus in studying morbid processes in them we are really studying a stage which is strictly analogous to human youth or adolescence.

Professor Smith has made prolonged experiments in bovine vaccination. The lesson of these experiments is that some immunity is produced. The science of public health has reduced the tendency to tubercuosis. Each of us is vaccinated *malgre lui*, but in spite of this therapeutic vaccination is of the greatest use in the great majority of cases with symptoms.

As said before, perhaps the main hope of extirpating tuberculosis, or at least of greatly diminishing its incidence, lies in preventive measures. Greatly improved hygiene of dwelling houses, factories and workshops will do much in this direction. In addition, of course, cases calculated to spread infection should be isolated. At the same and in the meantime the two great problems of modern bacteriology must be borne in mind, the application of the principles of immunity and the discovery of a hemotherapeutic agent. If preventive and bacteriological measures are carried on with energy and enthusiasm the prospects of a successful campaign against tuberculosis are bright.

THE HUMAN FOOT

The human foot seems a failure so far as keeping its shape is concerned, but, as is the case in other human shortcomings, there is much reason for this weakness in the abnormal conditions to which it must attempt to adjust. The arch of the foot is a recent development, for there is little trace of it in the other primates and it is the newly acquired structures which are least in condition for withstanding unnatural stress and strain. Flatfoot is simply a reversion to an ancestral condition. "The chief breakdown," as Sir Arthur Keith points out, "occurs at the midtarsal joint, particularly between the head of the astragalus and the rest of the tarsus."

"In the pronograde monkeys the midtarsal joint is a flexible joint, but in the orthograde gibbon one no longer sees a pure flexion movement in this joint. . . . However, even in the least arboreal of the great anthropoids, there is no arch; the sole of the foot is applied flatly to the branch which supports the weight of the animal. . . . The evolution of the human from a grasping foot was necessarily attended by the creation of a neuromuscular mechanism for maintaining the plantar arch. The muscles which became adapted for this new function were those for inverting, everting, and fixing the tarsal elements of the simian foot. . . . Flatfoot occurs when the postural function of the supporting muscles breaks down. Why the postural muscular mechanisms of the body are so apt to become disordered we do not know. When that of the plantar arch breaks down the human foot reverts to a condition comparable to that seen in the grasping arboreal foot of anthropoids. The midtarsal joint becomes again freely movable; the metatarsal elements of the foot become turned outward or everted

just as they are in the foot of an animal when seizing a branch."

With regard to hallux valgus Sir Arthur is refreshing in that he takes a larger view than that it is due to the shape of the shoe, for he has found that the great toe of the child or of the unshod races does not always follow the line of the inner border of the foot but may as often be directed outward or in a direction somewhere between these extremes. Of course, the shoe can be blamed for a bunion, but the outward direction of the great toe may be a normal condition.

TO PREVENT THE TURNING OF ROUND LENSES

Oh, what's the use, was our first reaction when we read this title to a paper by David W. Wells in the *Boston Medical and Surgical Journal* for November 6, 1924. Who, we thought, has ever known fashion to modify her whims and vagaries in response to appeals of reason, or to consider the health and comfort of her votaries? Round spectacle lenses with shell or celluloid frames have been the fashion now for a number of years. The manufacturers have the entire business in their hands, they are not anxious to add a mite to the costs of production unless shown that they can reap an additional profit thereby, the demand is almost universal and there are always cranks who object to everything. Can you blame them?

Round lenses are all right so long as they are simply spherical and made to correct myopia, hypermetropia, and presbyopia. But what Dr. Wells says of the evils resulting from them in cases of astigmatism is absolutely true. We discussed this editorially in July, 1919, and lined ourselves up with the cranks. The ophthalmologist spends hard work with good gray matter to determine the amount of astigmatism and its exact axis. To fill the prescription a cylindrical lens must be placed before the eye with the axis of the cylinder at a certain degree of the circle and, what is quite as important, must stay there. If the lens is turned so that the axis is at another degree of the circle, the astigmatism is no longer corrected, the lens is a misfit and perhaps worse than useless. Ever since round lenses in shell or celluloid frames became the fashion our prescriptions have been filled with them, the lenses often simply sprung into the frames with nothing to hold them in place except friction. Dr. Wells says that shell and celluloid frames give the most trouble because they shrink and swell with atmospheric changes, and he is probably right. It is certain that a lens can frequently be turned in its frame while wiping it. The relief a patient feels when he begins to wear the glass disappears as soon as the axis is changed and his symptoms reappear, perhaps in an aggravated form. As an example of this, Wells quotes the case of a patient who returned from Europe on account of eyestrain, which was found to be due wholly to such a turning of the lens.

Remedies are so simple as to seem ridiculous, yet they have appeared to be impossible to obtain. Unless the lens is perfectly round it cannot turn, the least change in shape is sufficient. Many devices have been suggested to hold the lenses in place, but each adds a trifle to the cost of production. Individual ophthalmologists who protested found themselves butting their heads against a stone wall. In groups they fared little better. In 1919 the Section on Ophthalmology of the A. M. A. adopted a resolution "recommending that frames with circular lenses be furnished with some device to prevent rotation of the lenses in their frames." There the matter seemed to drop.

Dr. Wells says that "if the spectacle wearers knew the danger, they would insist on being protected," but we have our doubts. The mover of the resolution referred to above called attention to the fact that a number of the members present were wearing just such glasses as those condemned. They were well aware of the danger. More than one had a little scratch in the edge of the glass and a corresponding one in the edge of the frame so that he could ascertain at any time whether his lens had been turned, and be able to replace it in position when necessary. Are patients less oblivious to danger than doctors? Don't they take chances, too?

But at the end of the paper comes a word of encouragement. Dr. Wells tells us that one of the largest optical companies in the country has agreed to furnish hereafter all round frames with some device to prevent the turning of the lens. This is good news. If the other manufacturers will follow suit the ophthalmologist can hope for better success in the relief of astigmatism than he has had for some years. We certainly hope that they will.

ANOTHER ALCOHOL SYMPOSIUM

The question of the therapeutic value of alcohol or whether it has any therapeutic value or whether it is at all times a poison, is a question which is never allowed by the medical profession to rest for long. It is in Great Britain where the chief concern with respect to this much discussed subject is being exhibited. Within the space of a year, the well known physiologist Prof. E. H. Starling has published opinions from distinguished authorities regarding alcohol. The English Medical Research Council in the early part of this year caused to be

ublished a thoroughly revised edition of a previous ublication on alcohol, its action on the human or-anism, and in October of this year the *Practitioner* evoted its issue to consideration of the alcohol ques-on from various standpoints.

The *Practitioner* records, perhaps, the medical iew of the matter rather than the scientific and on ne whole is probably in line with medical opinion in his country. While alcohol has fallen from its igh estate as a medicine, it is curious and instructive o note that many medical men cling to the belief hat alcohol possesses certain therapeutic virtues. t has been shown that the main action of alcohol is onfined to the nervous system and that it is a arcotic and not a stimulant, but it has been ex-lained too that in certain circumstances its sedative ffects may be useful. Its action as a narcotic, how-ver, is not due to any direct stimulation of the ervous system on the heart by the drug, but to its veakening of the excessive check on the heart's ction exercised by the nervous centres, and to its edative influence on the higher levels of the brain, elieving pain and anxiety and increasing the gen-ral comfort of a patient.

In the *Practitioner* the physiology and pharma-ology of alcohol is dealt with by Professor Starling vho propounds views similar to those given above. Sir Arthur Newsholme contributes a cogent paper n which he discusses prohibition in this country rom first hand knowledge. Being essentially a pub-ic health man he dwells on the matter from its ocial aspects and states that "The amount spent n drink in 1923 would have paid the rental of very house, farm, shop, factory and estate in Great Britain" and moralizes thus: "Evidently then, there need be no housing problem were there no drink problem."

The case against alcohol as a medicine except in he few circumstances already referred to is strong. n fact, most of the articles in the *Practitioner* which praise some points of view of alcohol as a nedicine, follow this by a qualifying but.

The conclusions to be gathered from this last ymposium on alcohol as a medicine is that it has ts value but a limited one as a narcotic. As a food much the same remarks may be made. It is readily absorbed into the system and can be used to supply a considerable proportion of the fuel needs of the body, and therefore may be of value in some condi-ions of disease and convalescence. There is, how-ever, a but here, as it is a food suitable only for such emergencies. Regarded physiologically alcohol taken n moderation with most people will do little appre-ciable harm but according to most scientific and medical authorities will do no good. On the other hand, alcohol taken to excess will do direct harm. The balance of evidence from the medicoscientific point of view is strongly against alcohol.

PARTIAL SURVEY OF TUBERCULOSIS CONTROL

In most civilized countries tuberculosis has been controlled to a considerable extent, and perhaps this control is more greatly in evidence in this than in any other country. In England and in certain parts of Europe, Germany, for instance, the efficient control of tuberculosis has been much hindered by the war and its aftermath. Where a sufficiency of nourishing food is not obtainable, tuberculosis is certain to flourish, and it probably is because the people of this country are able generally to obtain plenty of good food, that the fight against tuberculosis has been successful on the whole.

In an original article published in *Minnesota Medicine*, August, 1924, contributed by Dr. G. L. Tuohy, of Duluth, in which he discusses twenty years' observation of tuberculosis control in Minnesota, some very interesting points are dealt with. In his opinion the international congress held in Washington in 1908 had a most profound impression upon tuberculosis in America, and he thinks that what Newsholme said, "We are checking tuberculosis in England by hospitalizing the advanced cases," made the greatest impression upon those who attended the congress and supplied the keynote for the subsequent campaign in America and in Minnesota. It seems obvious that unless advanced cases, those in a contagious form, are isolated, infection must be spread. Therefore, the first step to take is to isolate advanced cases.

Again Tuohy draws attention to the knowledge which has been gained that truly incipient tuberculosis is found in childhood and it is on account of this happening that incipient tuberculosis is not found in our offices or sanatoria. While agreeing that adults may acquire tuberculosis and that children may be infected with the bovine bacillus, it still must be allowed that most children are inoculated by way of the bronchial tract from a human source. Thus it has been forcibly driven home to us that it is dangerous to house children and open cases of tuberculosis in the same room. It would appear, judging from the experience of Germany at the present time and of Ireland in days gone by, that the prevalence and virulence of tuberculosis depends chiefly on food and environment. Where both are bad or lacking in essential qualities, tuberculosis stalks through the land. Tuohy praises, and no doubt rightly, properly conducted sanatorium treatment and states that this form of treatment has played a con-

siderable part in the very encouraging decrease of tuberculosis in this country. In the prevention and treatment of the disease, isolation of open cases is absolutely necessary for the protection of the community. Sanatoria and colonies are useful adjuncts, but it appears that the main reliance for the prevention of the disease is good food and housing, that is, personal hygiene and appropriate diet. Tuohy suggests that general practitioners should again become interested in treating pulmonary tuberculosis. For although rest, food, fresh air, heliotherapy, and so on, have been advised in a general manner, these have been advocated in a too happy go lucky fashion and "what is needed is some of the same intelligent application of correct principles in private practice as is now seen in our special clinics and hospitals."

Finally he argues that it is necessary by every means in our power to place a hypothetical cordon about every positive sputum case, rendering it easy for the doctor to do his obvious duty in safeguarding his fellowmen. In order to effect this, every agency must be called upon and the general practitioner, in particular, must familiarize himself with up to date methods of treating pulmonary tuberculosis. Figures in this country with regard to tuberculosis testify what can be done by common sense measures and encourage the hope that by intensifying and improving existing methods and by introducing new ones and by instructing the general body of the medical profession how best to carry these out, aided by all the machinery of the public health services, pulmonary tuberculosis may be not only scotched but extirpated. The big epidemics have practically vanished or been ejected, and it is now time that two of the greatest scourges of civilization, tuberculosis and venereal disease, should be dealt with seriously and severely. To do this the public must earnestly cooperate with the medical profession. No half way measures will be of any avail and the money cost will be immense. But as a great statesman, some say Disraeli, said, "the health of the people is the highest law," and nothing should be allowed to stand in the way of its execution.

ADDITION TO POST-GRADUATE HOSPITAL

The property recently purchased and taken over by the New York Post-Graduate Hospital comprises the entire block front from Twentieth to Twenty-first Street on Second Avenue, and about two hundred feet on the cross streets. The building was that formerly occupied by the United Hebrew Charities. The addition of this tract makes the Post-Graduate the largest of its kind in the world. The basement of the new building will be used for a dining room for employees, and for clinics. The offices of the medical school and the library and reading room will occupy the main floor, and dining rooms for the staff will be on the second floor, which is connected with the other building by a bridge. The interns will be quartered on the third and fourth floors, and twenty-nine beds for patients will be installed on the fifth, which will make the hospital's bed capacity 410.

EYE ACCIDENTS LAST YEAR

In a report recently circularized by the National Committee for the Prevention of Blindness, it is stated that at least 4,456 persons in the United States had their sight either destroyed or seriously impaired during the last twelve months. Men and boys made up eighty-five per cent. of the victims, leaving only 604 of the casualties suffered by females. Industrial accidents were by far the most numerous; sixty-five persons were struck by baseballs; drinking wood alcohol destroyed or impaired the sight of thirty-five persons; thirty-one women burned their eyes with curling tongs; boys with sling shots injured the eyes of twenty-seven, and bows and arrows those of twenty-four; golf ball accidents impaired the sight of seventeen.

Obituary.

ANDREW R. WARNER, M.D.

Chicago, Ill.

Although Dr. A. R. Warner, executive secretary of the American Hospital Association, had been ill for nearly a year, his death came as a great shock, as he was apparently recovering. He died suddenly at his home in Deerfield, Illinois, November 27th, from heart disease.

Doctor Warner was born in Pulaski, New York, in 1875. He was graduated from Hamilton College in 1899 and from Western Reserve University Medical School in 1906. Subsequent to graduation, he practised medicine in Cleveland, Ohio, for a few years. The first hospital position he held was that of assistant superintendent of Lakeside Hospital, Cleveland. In 1913 he became its superintendent, a position he held until his appointment as executive secretary of the American Hospital Association on October 10, 1919.

Doctor Warner was always deeply interested and active in the development of organized hospital activities. He was one of the founders of the Cleveland Hospital Council and of the Ohio Hospital Association and served as president of the Ohio Hospital Association in 1918 and 1919. He was also instrumental in developing and organizing the American Conference on Hospital Service and served continuously as vice-president of the conference from the time of its organization. He was a Fellow of the American Medical Association. From the beginning of his hospital career he was interested in the work of the American Hospital Association, serving on several of its important committees. In 1918 he was elected its president. His earnestness and enthusiasm in the organization of hospital activities won for him nationwide and international recognition.

News Items.

Dr. Fowler Honored.—Dr. Russell S. Fowler was honored at a dinner on December third, marking the twenty-fifth anniversary of his service as chief surgeon of the Wyckhoff Heights Hospital.

Dr. Roussel Honored.—Dr. Albert E. Roussel, of Philadelphia, professor of medicine at the University of Pennsylvania, has been awarded the decoration of Chevalier of the Legion of Honor. He has previously received the decoration of the *Palmes Academique*.

Civil Service Examinations.—Examinations will be held for junior medical officer, assistant medical officer, associate medical officer, medical officer, and senior medical officer, applications being received until June 30th by the U. S. Civil Service Commission.

Harvey Society Lecture.—Dr. A. R. Dochez, professor of medicine, College of Physicians and Surgeons, Columbia University, will deliver the sixth Harvey Society Lecture at the New York Academy of Medicine, on Saturday evening, January 17, 1925. His subject will be "Etiology of Scarlet Fever."

Cancer Study Award.—The commission for the distribution of the prize for cancer study founded by Dr. Sofie A. Nordhoff-Jung, in agreement with the foundress, has resolved to distribute the prize from now on only every two years to the double amount of the sum allotted heretofore, that is, One Thousand Dollars. The next prize will reach distribution in 1926.

Warren Triennial Prize.—Announcement is made by the general executive committee of the Massachusetts General Hospital that dissertations on some special subject in physiology, surgery, or pathology, in English, French, or German, will be received until April 15, 1925, in competition for the Warren Triennial Prize of five hundred dollars. Details may be obtained from the hospital.

Dr. Fuhs Honored.—Dr. Jacob Fuhs, of Brooklyn, was the guest of honor at a dinner given by four hundred of his friends, at the seventy-fifth anniversary of his birth and the fiftieth of his graduation in medicine, from the College of Physicians and Surgeons. Six volumes of the *Annals of Medical History* were presented to him. Dr. Frank F. Jennings making the presentation speech. Representatives were present from the medical societies with which Dr. Fuhs is connected, and several addresses were given.

Health Examinations.—The Medical Society of the County of New York has issued a pamphlet on periodical health examinations. In it are listed courses in the technic of conducting such examinations, to be held at the Post-Graduate Medical School (information to be obtained from the Dean). Courses are also contemplated at the Cornell Medical School and at the College of Physicians and Surgeons. There are also to be given a series of addresses on Tuesdays and Thursdays in January, at four o'clock at the Academy of Medicine.

Training of Tuberculosis Nurses.—The Public Health Committee of New York Academy of Medicine has passed the following resolution regarding the training of nurses in the care of the tuberculous sick:

WHEREAS, There is a well recognized and widespread need of trained nurses for the care of tuberculosis patients, and

WHEREAS, The nursing of such patients requires a special technic which, as a rule, is not taught in the course of the training of registered nurses for the reason that most of the hospitals in which such nurses are trained do not take cases of pulmonary tuberculosis, and

WHEREAS, It is found that registered nurses as a rule give themselves up to the care of pulmonary tuberculosis with great reluctance, or not at all, and consequently there is a very great shortage of properly qualified nurses to take care of this large group of cases, and

WHEREAS, The chief source of supply of nurses for the care of pulmonary tuberculosis is from women who have themselves had tuberculosis and been cured of it, therefore be it

Resolved. That the Public Health Committee of the New York Academy of Medicine favor an amendment to the Nurse Practice Act which shall give official recognition with a suitable title to graduates of training schools operated in conjunction with tuberculosis sanatoria in this State, provided the sanatoria meet the requirements to be established by the Board of Regents and provided the course of instruction be of at least two years' duration and that it meet also any specific requirements for the training of nurses to care for the tuberculosis sick, which shall be formulated jointly by the Board of Regents and representatives of the tuberculosis sanatoria in the State.

Official recognition of this type of nurse with a suitable title would be similar to the recognition accorded to graduates of training schools in the State institutions, or institutions under the visitation of the State Hospital Commission. (Chapter 742—Public Health Laws of 1920. Paragraph 252-c).

Postgraduate Study in London.—The Fellowship of Medicine and Postgraduate Medical Association, London, announce a number of postgraduate courses on special subjects to be given in various London hospitals, during the coming year. Detailed information may be obtained from the secretary of the Fellowship of Medicine, 1 Wimpole street.

Reports of Typhoid Cases.—Owing to the considerable prevalence of typhoid fever in New York, the Public Health Committee of the New York Academy of Medicine suggests to the Fellows of the Academy that they report their cases in detail and cooperate in every possible way with the Department of Health, in its efforts to discover the cause or causes of the present outbreak.

Personal.—Dr. J. S. Rodman, secretary-treasurer of the National Board of Medical Examiners, has accepted the chair of surgery in the Woman's Medical College of Philadelphia.

Dr. Herman Goodman gave the first of a triology of talks on tropical dermatology before the Clinical Society of the New York Skin and Cancer Hospital on December 26th. His subject was "Frambesia Tropica and Syphilis."

Dr. Max Einhorn, New York, has been elected corresponding member of the "Société de Médécine de Paris."

Dr. Walter H. Brown, who has been director of the child health demonstration at Mansfield, Ohio, will take charge of the demonstration to be made in Marion County, Oregon. He will be succeeded in Mansfield by Dr. William de Kleine, health officer of Saginaw, Michigan.

Meeting of Westchester County Medical Association.—The next meeting of the Westchester County Medical Association will be held on the evening of January 20th, at St. Johns Hospital, Yonkers. Dr. Willy Meyer will speak on "Advanced Pulmonary Tuberculosis,—a Borderline Disease;" and Dr. S. Adolphus Knopf will speak on "Something Old and Something New in Pulmonary Tuberculosis." Under the former he will discuss the early recognition of the disease, and under the latter he will demonstrate his new method of controlled diaphragmatic breathing as an adjuvant in the rest cure.

Meeting of Medical Association of Greater New York.—At a meeting of the Medical Association of the Greater City of New York, to be held on the evening of Monday, January 19th, at the Academy of Medicine, Dr. Haven Emerson will speak on "The Dependence of Increased Life Expectancy Upon the Private Practice of Preventive Medicine." Dr. S. Adolphus Knopf will present a paper on the subject of "The Psychology, Psychopathology, and Psychotherapy in Tuberculosis in Civilian and Military Life."

Society News.—At a recent meeting of the American Stomatological Association, the following officers were elected: Dr. Homer E. Smith, New York, president; Dr. Oliver T. Osborne, New Haven, Connecticut, and Dr. Noah Philip Norman, New York, vice-presidents; Dr. Robert H. Rose, New York, treasurer, and Alfred Asgis, D.D.S., New York, secretary.

The Yorkville Medical Society of New York has elected the following officers: President, Dr. Charles N. Gelber; first vice-president, Dr. Adolph Stern; second vice-president, Dr. I. Glassman; corresponding secretary, Dr. M. Meltzer; recording secretary, Dr. S. Morse; treasurer, Dr. H. O. Klein; Trustees, Dr. A. S. Blumgarten, Dr. M. F. Goldberger, and Dr. A. Kahn; chairman of committee on ethics, Dr. J. L. Wollheim; chairman of committee on legislation and economics, Dr. Henry Keller; chairman of committee on ways and means, Dr. M. Peshkin; chairman of committee on admissions, Dr. A. Shoen; chairman of committee on new members, Dr. M. Frantz.

The Eastern Medical Society of New York has elected the following officers: President, Dr. Nathan Ratnoff; first vice-president, Dr. A. J. Rongy; second vice-president, Dr. Joseph Bieber; treasurer, Dr. J. F. Saphir; recording secretary, Dr. I. Seth Hirsch; corresponding secretary, Dr. Harry E. Isaacs; trustees, Dr. Abraham Strachstein, Dr. Israel Strauss (for one year); chairman of committee on ethics, Dr. L. J. Ladin; chairman of committee on legislation, Dr. M. Keschner; chairman of committee on admission, Dr. J. Barsky; chairman of committee on new members, Dr. M. R. Robinson; chairman of committee on medical economics, Dr. Emil Altman.

Jubilee of the London (Royal Free Hospital) School of Medicine for Women

MISS LOUIE M. BROOKS
London,
Warden and Secretary to the Hospital

Fifty years ago the medical register of Great Britain contained the names of only two women. Of these, one had attained her place through a foreign qualification; and the other had slipped through a loop hole in the charter of a qualifying body. The roads by which these pioneers had entered the medical profession were definitely barred against all who might try to follow. No university and none of the Royal Colleges would admit women either to medical education or examination. Today there are over two thousand women on the register. They hold important hospital appointments, in the institutions peculiarly their own, in special hospitals and in certain general hospitals; they hold distinguished posts in various government departments, under municipalities, in the Women's Indian Medical Service, and under the chief missionary societies; and they are succeeding professionally and financially in private practice.

While several factors contributed to the resolution that has been accomplished within the last half century, there can be no doubt that the leading part was played by the London School of Medicine for Women whose jubilee was celebrated in November.

The London (Royal Free Hospital) School of Medicine for Women (University of London). Founded in 1874.

It is interesting to note that America played an important part in the developments that led to the founding of the school. The first woman doctor of modern times was Elizabeth Blackwell who emigrated with her family from Bristol to America when still a child. On the death of her father, Elizabeth Blackwell took up teaching in Ohio. Moved by a desire to be of greater use to women she determined to take up the study of medicine, in spite of her strong distaste for everything connected with illness. She succeeded in obtaining entry to the University of Geneva, New York State, by a resolution of the students that "one of the radical principles of a Republican Government is the universal education of both sexes." "In extending our unanimous invitation to Elizabeth Blackwell," continued the resolution, "we pledge ourselves that no conduct of ours shall cause her to regret her attendance at this institution"—a contrast to the spirit in which the pioneers in England were received later.

After her qualification, Elizabeth Blackwell returned to England to assist the movement there for the medical education of women. At one of her lectures she notes that her "most important listener was the bright intelligent young lady whose interest in the study of medicine was then aroused—Miss Elizabeth Garrett." On her return to America she found in the first class she conducted at the College of the New York Hospital for Women, the third of the great pioneers in medicine—Sophia Jex-Blake.

Although Elizabeth Garrett—better known as Mrs. Garrett-Anderson—had passed the examination of the Society of Apothecaries in 1865 and thus obtained a place on the medical register the society had altered its regulations so as to prevent the admittance of other women. Faced with this situation Sophia Jex-Blake went to Edinburgh and endeavored to obtain a medical education at the university there. For four years she led a little party of women through all the trials and difficulties that were put in the way. She was first rejected, then accepted, then rejected again. She was mobbed by the male students, sued for libel, involved in a legal action against the University to secure admission to examinations, and finally ploughed in an examination. This rebuff was followed by the sustaining of the University's appeal against the Court's judgment, the door of the University was definitely closed to women, and the pioneer and her companions found themselves further back than when they started. Never did a gallant attempt end in more disastrous failure.

Beaten at Edinburgh, Sophia Jex-Blake came to London and achieved a success that gives her forever an outstanding place in the history of women in medicine. Almost single handed, and in face of tremendous difficulties she gathered together a body of sympathizers and, with £1,300 as "working capital," founded the London School of Medicine for Women in 1874.

By 1877, when the first thirty-seven women had completed their curriculum the school seemed as forlorn a hope as ever. Although an Act of Parliament of the previous year had given medical examination boards power to admit women to examination, none had taken advantage of it. No hospital would admit the women to clinical instruction. The meagre funds had been exhausted and classes were suspended.

Suddenly the darkness lifted. A medical college

in Ireland admitted Sophia Jex-Blake and her companions to examination, through which they passed on to the medical register. At last a qualifying examination was definitely open to women. Within a few months the Royal Free Hospital, greatly daring, agreed to take women students for clinical work in its wards; and the University of London decided to admit women to examination.

Although Sophia Jex-Blake returned to Edinburgh to engage in private practice, her school in London went triumphantly on its course. A public appeal for funds raised £5,000 within a few months and teaching was resumed.

For the last fifty years the story of the school and the story of women in medcine has been practically one. Year by year the students have more than fulfilled all expectations, and the school has today as high a percentage of academic distinctions as any other. In 1897 Mrs. Garrett-Anderson, then dean of the school was elected president of the East Anglian Branch of the British Medical Association, and her year of office marked almost the complete and final entrance of women into the inner shrines of the medical profession. Practically the last barrier fell when, in 1909 the Royal College of Physicians and the Royal College of Surgeons opened their doors to women.

The school's connection with the development of medical services for the women of India has been a close one. When the first dispensary for Indian women was opened in Bombay, it was Dr. Edith Pechey, one of the Edinburgh pioneers who was put in charge. A few years later Mrs. Scharlieb, the doyenne of medical women in the Empire today, and still a practising specialist in Harley Street, became a lecturer at the Madras Medical College, a post which she quitted in 1897 to begin a teaching connection with her old school in London, of which she is president.

The school still stands on its original site in Hunter Street, Bloomsbury, although today far different from the two old houses in which Sophia Jex-Blake started its activities in 1874. The school was rebuilt in 1898 and opened by the late King Edward and Queen Alexandra. Before long the buildings were again found to be inadequate and a large extension, opened by Queen Mary, was added in 1916. The school has a graduate roll of over eleven hundred students; over four hundred women are studying within its bounds at the present moment; and it is able to accommodate an entry of seventy-five new students every year. The Royal Free Hospital still maintains the closest connection with

Outpatient Department, Royal Free Hospital

the institution it fathered in the difficult days of 1877 and, together with other affiliated hospitals, provides the necessary clinical experience for the students and also the house appointments after graduation which are an essential part of medical education.

In connection with the jubilee of the school an endowment fund of £60,000 is being raised to found three chairs—anatomy, physiology and pathology—to be named after Elizabeth Blackwell, Elizabeth Garrett-Anderson and Sophia Jex-Blake. Headed by a donation from Her Majesty The Queen, over £25,000 has already been raised. Many promises of help have been received from America and it is hoped that a substantial sum will be received from American citizens toward endowing the chair in memory of the medical pioneer whose success in America inspired the movement that has given women their place in medicine today.

Foreign Correspondence.

LONDON LETTER

(*From our own correspondent*)

LONDON, *November 21, 1924.*

HEALTH OF SCHOOL CHILDREN IN ENGLAND AND WALES

The annual report of Sir George Newman as the Chief Medical Officer of the Board of Education, entitled "The Health of the School Child in 1923," has just been published. The author begins by pointing out that "the restraining conditions under which the School Medical Service suffered in 1922 owing to the need for national economy began to be less oppressive in 1923. By the middle of the year the board was in a position to encourage authorities to consider reasonable improvements and expansions of their activities." During the year 1923 the number of elementary school children subjected to routine medical inspection was 1,754,919, and an examination of the returns furnished by the 212 local education authorities out of a total of 317 who supplied statistics shows that 19.4 per cent. of the children were found to be suffering from more or less physical defects which required treatment. The total number of defects treated, or under treatment, during the year, excluding dental defects and uncleanliness, in England and Wales, was upwards of 880,000. The great bulk of the medical treatment was provided at the 1,076 school clinics established by the local education authorities, or at 390 hospitals with which the authorities had made arrangements; but some of it especially in the rural districts was furnished by private medical practitioners or otherwise. For example, there were 473,000 minor ailments treated under the treatment schemes of authorities

and 63,000 otherwise; there were 157,000 errors of refraction of vision dealt with under schemes and 14,000 otherwise; there were 122,000 pairs of spectacles prescribed by authorities and 12,000 by other persons or agencies; there were 32,000 operations for adenoids or enlarged tonsils in the school clinics and 15,000 in hospitals or private practice, and there were another 32,000 cases of disease of nose and throat which received nonoperative treatment; 37,000 cases of ringworm were treated by the authorities and 6,000 cases otherwise. In 1923 the London County Council provided treatment for 218,000 children. In addition to the morbid conditions or physical impairment found at medical inspection there is a large group of children suffering from physical or mental defect, blindness, deafness, epilepsy, feeblemindedness, tuberculosis, and crippling, estimated approximately at 130,000, excluding socalled delicate children. For these children there are 530 special schools or sanatoria, accommodating 41,000. Systematic dental inspection reveals the fact that more than two thirds of the whole school population of England and Wales are suffering from dental disease. Dental inspection and treatments are being carried out, to a limited extent, by 240 education authorities in England and Wales; during the past year the total number of children dentally inspected was 1,557,249, of whom 1,077,774, or 67.9 per cent., were found to be in need of treatment. The actual number treated was 615,491, or approximately one tenth of the school population of the country.

SOME DISEASES COMMON TO CHILDHOOD

The opening address at the first of a series of discussions on the special character of disease during childhood adolescence, the climacteric and old age, held by the Chelsea Clinical Society, was delivered by Dr. Eric Pritchard, on November 18th. He dealt with some diseases common to childhood and considered the subject from a somewhat novel viewpoint. He described the special mechanisms on which the young child depends for protection against the disease provoking conditions of its environment mechanisms which, although the same nature as those possessed by the adult, are still in an immature and undeveloped state. The conception that disease or ill health is the result of somewhat clumsy and painful attempts to accommodate the individual to the conditions of the external environment was the avowed object of Dr. Pritchard's remarks, and he developed the argument by explaining the main reason why symptoms and symptom complexes were different in children from those manifested in adults. It was because in the two cases the mechanisms whereby these adjustments with the environment were secured were in different stages of development: in the adult they were efficient and well trained, in the child they were immature and inefficient. There were two additional reasons why the reactions of the child to the environment should be different from those of the adult and these were as follows: The infant especially, and the child, to a lesser extent, lived in a special and sheltered world of his own which was chosen for him by his mother, to the best of her ability in accordance with tradition and the dictates of nursery hygiene, and the other reason was that the child had very little control of that environment himself; he could not run away from it, or alter it to any material extent. In short, infancy and childhood are not long enough to enable the individual to learn how to adapt himself to his environment. It was pointed out that most of the pathological reactions or symptoms to which human flesh was heir were due to either food causes or to infective disease. In considering the symptoms which result to the child from food injuries, Dr. Pritchard did not deal with that perhaps overdiscussed matter, the avitaminoses, but considered the more commonplace type of symptoms resulting from an actual excess of food. The point is insisted upon that the protective reactions on pathological results of overfeeding take quite a different form in the child and in the adult, because in the one case the mechanisms for intercommunication, cooperation and the division and control of labor were in a very rudimentary stage of development and because in the other they were very highly organized. An infant or child who consumed too much food or unsuitable food would probably be saved from the more serious consequences of such indiscretion by a lesser evil, the violent reaction of the stomach, it would either vomit or have diarrhea or would show some other evidence of a breakdown of liver, kidney or general metabolic function. The infant relied largely on his motor mechanisms and on his skin and mucous membrane. The older child utilized his lymphatic system more largely. The adult, in whom the principle of the division of labor and cooperation was better developed, used all his mechanisms of defence with economic impartiality, delegating as far as possible the duty of defence to the humblest and least specialized cell workers, the connective tissues. Attention is drawn to the different forms exhibited by rheumatism in the infant, the child, and the adult.

Dr. Pritchard said it was his belief that rheumatism could occur in infants and young children, and that the adult was not exempt from the causes and effects of rickets. The address further pointed out that while the greater part of childhood was occupied with the acquisition of immunity, not only to the common infective diseases but also in acquiring immunity to the very varied bacterial fluid which infested the epithelial and mucous surfaces and of which adults were the safe and unconscious carriers. He added, however, that many infants died in the effort to become safe carriers.

BIRTH CONTROL AND THE CHURCH

Lord Dawson of Penn, in giving evidence a short time ago before the Birth Rate Commission of the National Council of Public Morals, argued that discussion of the principles and the methods of birth control should be kept separate. The methods of birth control should be set forth to those people alone whom they properly concerned. Regulation of the number and the occasions of child births had been brought about by several factors: 1, increasing density of population; 2, increasing sense of the value of child life and of the responsibility of parenthood; 3, desire of parents to equip their children in body and mind to the best of their ability; 4, social and domestic difficulties in the homes of educated people; 5, desire of woman for a larger share of the world's working, a share she could not

ake if her best years were exclusively absorbed in naternity. He asked if it were desirous to restore he conditions of former generations, namely, large amilies with their high death rates and rough and umble methods? If the answer were in the negative then the birth rate must and would be controlled. He pointed out that church authorities evaded the eal problem: they half apologized for sex love, or t other times seemed to ignore the existence of his dominating force of the world. Finally he drew ttention to the fact that birth control was spreading to the industrial classes, and there was every evidence that it had and would spread continuously. The Roman Catholic Church, with its compact organization, had failed to stop it. Nothing but convincing reasons that it was harmful or wrong, or both, would command any attention from the people. Mere statements that it was immoral, was contrary o the teaching of Christianity, or was condemned by the Bible, would only bring disrepute on those who made them, and especially among the young, who mattered the most.

NEW BOOKS

An excellent book written by Percy Hall, M.R. C.S., L.R.C.P., with introductions by Sir Henry Gauvain, M.A., M.D., M.C. (Camb.), and Leonard E. Hill, M.B. (Lond.), F.R.S., has been published recently by William Heinemann, Ltd., London.

The subject dealt with is ultraviolet rays in the treatment and cure of disease, and while it is a matter which has been widely discussed of late Dr. Hall has produced the clearest and most practical thesis on the question brought out as yet.

Another book published by the same firm the other day is a posthumous work. Its author, Dr. R. Murray Leslie, died shortly after the completion of this work on pneumonia. Dr. Leslie was easily one of the best medical writers in the English language from all viewpoints. He was an exceptionally brilliant man and one who not only possessed the knowledge but was able to clothe it in good English and with a fine literary style. Dr. J. Browning Alexander has thoroughly revised the book and brought it up to date and the monograph should prove of use to the medical profession.

LATIN AMERICA LETTER

(From our own correspondent)

PANAMA, *December 15, 1924.*

SEVENTH PAN AMERICAN SANITARY CONFERENCE

The Seventh Pan American Sanitary Conference convened at Havana, Cuba, on November 5, 1924, and closed its sessions on November 15, 1924, after electing Dr. Carlos Enrique Paz Soldan president. Dr. Paz Soldan is professor of hygiene in San Marcos University and is considered one of the foremost hygienists of South America. He has not only studied his profession in his own and many other countries, but has also produced a great volume of literary work chiefly upon his branch of science. The next meeting of the conference will be held two years hence at Lima, Peru. Among the most important matters taken up by the conference was the Pan America maritime sanitary code. This document was accepted by the eighteen nations represented at the conference with relatively few amendments as has been previously stated in these columns. The text of the code, which is in effect an international treaty, was prepared by the Pan American Sanitary Bureau at Washington, D. C. The conference also approved a model law with respect to the production and manufacture of foods and drugs with a view to its enactments by the various Governments of Pan America for the purpose of establishing uniform standards and guarantees.

ILLITERATE CHAUFFEURS

The general superintendent of public instruction of the Dominican Republic is establishing classes in Santo Domingo as well as in the smaller cities and towns for the purpose of teaching illiterate chauffeurs, of which there are many, to read and write. An opportunity will also be taken in the classes to determine whether or not the chauffeur is mentally and physically fit to be entrusted with a public vehicle of the potentialities of the automobile.

MEDICAL SOCIETY OF LA PAZ, BOLIVIA

Several prominent physicians of the city of La Paz have recently organized themselves into a medical society for the purpose of improving the medical profession by means of scientific meetings and discussions and the presentation of the clinical cases for study. The society will publish a medical bulletin and will cooperate with the Government in the preparation of a sanitary code and in carrying on a popular propaganda for public health.

ANTISMALLPOX CAMPAIGN

The Bolivian Red Cross recently designated a number of its nurses for the purpose of vaccinating all pupils in the girls' schools of La Paz. This was done with the dual idea of controlling smallpox and increasing the public appreciation of vaccination.

URUGUAYAN BACTERIOLOGICAL INSTITUTE

Professor Kurt Schern has been engaged by the Uruguayan Government as director of the Bacteriological Institute of the Montevideo School of Veterinary Medicine. Professor Schern, who has come from Germany to do this work, will, under the terms of his contract, lecture on infectious diseases and bacteriology and conduct research in the diseases of livestock. He will also be in charge of the work of manufacturing vaccines and antitoxic sera.

URUGUAYAN CHILD WELFARE

The National Council of Hygiene of Uruguay has created a special section of child hygiene which will have as its function the inspection and improvement of the health of young children. It will endeavor to collect and preserve birth and mortality statistics as applied to children and will make research into the causes of infant mortality and the means to be adopted for its prevention. The new section is taking active steps in the prevention of communicable diseases of children and has arranged for an annual baby week including public conferences and health competitions of children. The National Council of Hygiene is forming a League of Little Mothers

composed of girls over twelve years of age, who will be given vacation courses on the hygiene, care and feeding of young children. It is hoped that through this league mothers may be organized for the purpose of taking courses of practical demonstrations in the economical and proper preparation of dietaries for children.

THE WHITE SLAVE TRAFFIC

The President of Uruguay has approved a law whereby the Government of Uruguay becomes a signatory to the International Convention on White Slave Traffic signed at Geneva, Switzerland, on September 30, 1921.

PARAGUAYAN CHILD WELFARE

A program of child welfare which will bring into cooperation the services now existing in Asuncion, Paraguay, and add new functions was formulated in June by a special committee of medical practitioners. The program includes the appointment of four visiting nurses, the establishment of a prenatal clinic, a gynecological clinic in the National Hospital, the medical inspection schools and the free treatment of trachoma. The free milk centre and the pediatric clinic will be extended to include instruction in child care. Steps will also be taken in the protection of the control of tuberculosis in young children and in the prevention of ophthalmia neonatorum by the enactment of an ordinance making the use of silver nitrate in the eyes of all newly born children obligatory.

CHILDREN'S HOSPITAL

Quito, Ecuador, has taken the initial steps looking to the erection of the Baca-Ortiz Hospital for poor children made possible by a donation from Mr. Hector Baca. There has recently been created in the Republic the Ecuadorian Child Welfare Committee, largely through the efforts of Miss Suzanne Ferriere, general secretary of the International Union of Child Welfare. On the occasion of her recent visit to Ecuador, she was unanimously elected the honorary president of the new society. Another movement which is serving to increase child welfare is the establishment of Leagues of Kindness in the public schools of Ecuador. The membership is confined to school children, who bind themselves not to lie, to protect the weak, comfort the unhappy and respect the aged and sick, and to be polite and courteous, and to be kind to animals. Anyone who has traveled in Latin America has been struck with the excessive brutality and cruelty with which domestic animals are treated. Many of the best thinkers of Latin America have come to the conclusion that there can be no really large advance in public health work until this is overcome because man cannot realize the sacredness of human life and health unless he has first a proper idea of the necessity of protecting the health of lower animals and treating them kindly.

CHILD WELFARE IN BRAZIL

The Child Welfare Institute of Rio de Janeiro, which was founded twenty-five years ago by Dr. Moncorvo Filho, established in 1921 a prenatal and infants' dispensary. During the three years of its existence it has treated several thousand women and babies, has performed many Wassermann tests and given treatment for venereal diseases where indicated. It is stated that the work of this institution has reacted very favorably on the health of children in Rio de Janeiro.

CHILE'S ADVANCE IN CHILD WELFARE

For several years child welfare has been receiving increased attention in the larger cities of Chile, notably in Santiago and Valparaiso. Arrangements have recently been made whereby the Manuel Arriaran Hospital will care for tubercular children. Similar arrangements have been made with the hospital of San Jose. The San Jose de Maipo Sanitorium is not yet open, but as soon as sufficient funds for its operation are provided, it will be put in operation since it is located in a climate which is believed to be very favorable to the treatment of the disease. In Santiago the *gotas de leche,* or free milk stations, are continuing their operation in the issuance of milk to children, the vaccination of children against smallpox and the treatment of mothers and children for syphilis. Maternity care is provided in the *asilo maternal* or maternity house. The baby's layette section provides clothing for poor babies and the *marmita* or free lunch section provides lunches for poor school children. On June 21, 1924, the president of the National Council of Women, Dr. Ernestina Perez, began a series of lectures on child care in the public schools of Santiago.

VIENNA LETTER

(*From our own correspondent*)

Vienna, *October 31, 1924.*

NEW SUBJECTS IN THE VIENNA UNIVERSITY CURRICULUM.

The new semester of the Vienna University has brought, besides the obligatory and conventional lectures, a whole series of new lecturers and new subjects. Only a few chairs are vacant, and these on the medical faculty. An interesting new subject is the series of lectures on the Essence and Development of the German National Genius. The lectures are open both to students and nonstudents and to all faculties. Another series of lectures will deal with the Justification and Limitation of the National Moments in Culture and Education. A new feature is the introduction of lectures on radiotelephony, which will be delivered by Professor Haas and can be attended by all classes of students. Professor Schmidt will lecture on the Study of Climatics in the Alpine Countries, Professor Reche announces a series of lectures on Anthropological Practicum, and Professor Czermak on the Races and Languages of Africa. The Vienna University had 8,074 students in 1923; among these 2,212 law students (seventeen women), 2,380 medical students (348 women), the philosophical faculty has been attended by 2,205 students (549 women), 156 Catholic theological, and sixty Evangelical students (two women). Out of the total number of students there were 1,072 special students.

THE VOICE OF FAMOUS MEN

In the uppermost story of the physiological institute of the Vienna University two rooms are oc-

cupied by the collection of phonographic records of the Scientific Academy, a very rich collection of records. There are records reproducing the sighing of the wind, the howling of a beaten dog, the shrieking of starving cannibals, and also beautiful airs sung by artists, whose vocal organs are the wonders of the human organism; songs of notable actors and actresses, speeches of diplomats, the monotonous talking of the late Kaiser Francis Joseph, and selections from the lectures held by prominent members of the professorial board of the Vienna University. The voice of every medical professor is preserved and also that of prominent students; also the foreign guests of the University and particularly that of the medical faculty. Notable among them is the record of Professor Einstein. He speaks gravely even into the phonograph. His voice is hard and sounds like the program speech of a candidate before the elections. Rabindranath Tagore could not be persuaded to speak into the machine. He wanted to sing only his own poems. Thus the record has perpetuated Indian songs, that nobody understands.

A NEW METHOD OF NARCOSIS

In some of the Vienna surgical clinics a new method of narcosis is being experimented with. The method started in Paris. Dr. Fredet intended to confirm on ground of accurate measurements, out of the diverse narcotizing drugs, which one is the best economizer of chloroform. The most advantageous drug proved to be somnifen, a mixture belonging to the veronal group, and up to now it has been chiefly used by midwives. This drug, somnifen, if injected into the vein is capable of lessening the amount of chloroform by fifty to sixty per cent. and finally to one hundred per cent., that is, even in operations of long duration chloroform could be dispensed with. The whole method of Fredet is nothing else than giving a preliminary morphine-scopolamine injection followed by an intravenous injection of somnifen to the patient to be operated on. The procedure is quick and simple and is advantageous from the point of view of the operating surgeon, because it is not necessary for him to divide his attention between operation and narcosis; he requires fewer assistants and the operating theatre is devoid of the noxious ether and chloroform vapor. From the point of view of the patient it is to his advantage that he need not fast before operation and postoperative vomiting does not occur. The experiences of the Vienna surgeons have not yet been published but it is hoped that their results will be at least as favorable as those of the French surgeons who use this method extensively.

BRUTAL MURDER OF A DOCTOR

In the town of Türunitz, in the vicinity of Aussig, the town physician, Dr. Anton Quoika, sixty-six years of age, has been murdered in a brutal manner. In the waiting room of his office there were about ten patients. As the doctor did not commence his consultations at the usual time the patients became impatient, and opened the office and found the old, jovial doctor on the floor, in a great pool of blood. He had received five mortal blows on his head, which had been inflicted by the leg of a stool. The culprit escaped. On the same afternoon the murderer, a late patient of the doctor, was arrested. He knew that the doctor's family was absent and that he was alone and murdered him to rob him.

THE DEATH OF PROFESSOR WILHELM ROUX

This celebrated anatomist, who has been teaching anatomy also in the University of Vienna, died in his seventy-fourth year of age. He was born in Jena, Germany, and studied in Germany, having been recognized as an extraordinarily ambitious student of the late Professors Ernst Haeckel and Rudolf Virchow. He was promoted to the rank of doctor of medicine in 1877 in Jena, and afterwards studied natural sciences for a year and then published his first dissertation on the Ramification of the Blood-vessels. This work aroused the interest of the whole medical world and at once made his name world famous. His greatest work was *The Fight of the Parts in the Organism.* This work was so important that Charles Darwin declared it as most important for the building up of his theory of the history of development. After having completed his researches he occupied in 1880 the chair of anatomy in the University of Breslau and in 1886 he came back to the Innsbruck (Austria) University, where he stayed till 1897. Then he was invited to the University of Halle, where he stayed until his death.

MASS POISONING CASES IN AN INFANTS' HOME

In the Country (Lower Austria) Infants' Home in Baden (not far from Vienna), two children fell ill with diphtheria. The rest of the children who came in closer touch with these, altogether thirty-six of them, have been duly immunized by having been inoculated with toxin-antitoxin mixture (according to the method of Professor Kassowitz, of the Vienna University). After seven days seven children have shown serious reactions. Six of them died during the period from September 16-29, despite the medical aid which was given them promptly. All manifestations pointed to poisoning. The postmortem examination, carried out by the city police pathologist, declared that all the six cases were poisoning with diphtheria toxin. The inoculated serum was supplied by the Serotherapeutic Institute in Vienna. The case did not get into the papers until the end of October, when the lay press handled it with such animosity that Professor Pirquet had to write on the subject in a leading daily paper. The investigations resulted in the finding that the Serotherapeutic Institute, owned by another company, had been very careless in the handling of the serum. It had been sold without the date of expiration of efficacy having been printed on the label. The stoppers of the bottles containing the serum left much to be desired; in some cases they did not close the bottles completely. The medical papers have urged the passing of a law that only the state shall be allowed to manufacture sera and vaccines, under the control of the expert professors of the university, and then such occurrences will surely be avoided. In consequence of this sad occurrence the confidence of the public in vaccines and sera has been very much shaken so that doctors have difficulty in persuading parents that this case was only an unfortunate accident.

Book Reviews

TREATMENT OF TUBERCULOSIS

Handbuch der gesamten Tuberkulose-Therapie. By Prof. Dr. Ernst Loewenstein. Band II. 190 Illustrations. Berlin und Wien: Urban & Schwarzenberg, 1923. Pp. 1,000.

It would be impossible to review each and every one of the numerous chapters in this volume, so all that can be done is to refer the student to the marvelously complete descriptions of the various phases of tuberculosis science. Nearly two hundred pages are devoted to the specific treatment of tuberculosis. The author seems to favor the new tuberculin (Bazillen emulsion) and the albumen free tuberculin. In no textbook on tuberculosis, at least not to the knowledge of the reviewer, are the complications of pulmonary tuberculosis or the primary tuberculous infections of other organs so thoroughly treated as in this textbook. The late Prof. Zuckerkandl, of Vienna, gives an excellent description of tuberculosis of the kidney and bladder, and Lichtenstern does the same for tuberculosis of the prostate and testicles. Under tuberculosis of the skin by Professor Volk, besides the treatment with the aid of tuberculin, we see mention made of chemotherapy, surgical methods, heliotherapy, phototherapy, x ray treatment, radiotherapy and local freezing treatment. With the same thoroughness is described the treatment of the tuberculous female genital organs and tuberculosis of the eye, nose, mouth, pharynx, and larynx.

The surgical treatment of pulmonary tuberculosis, including artificial pneumothorax, is thoroughly gone into by numerous authors. The late Prof. Chr. Saugman, of Denmark, contributed an excellent essay on the technic of artificial pneumothorax. In the historical review of this treatment, it is gratifying to see credit given to our late Murphy of Chicago, for European authors are likely to forget the fact that Murphy was a pioneer of artificial pneumothorax fully as much as Forlanini. There is nothing new advanced either in the technic or in the indications or contraindications for artificial pneumothorax. The conclusions as to the results, given by Prof. Carpi, of Milan, are interesting, although not corroborated by many observers. Carpi maintains that pneumothorax can definitely cure pulmonary tuberculosis, that the treatment can be stopped after a relatively short time, and that the phthisical lung, cured in this way, can resume its function if it had been allowed to remain at rest long enough. According to him, pulmonary tuberculosis can be lastingly treated and cured in shorter time by this than by any other method. He gives the average time necessary to obtain an absolute cure as six months according to Feldmann, and eight months according to Saugman.

As a relatively new contribution brought out in this volume we must mention endocrinology in tuberculosis by Prof. Wiesel. He considers Addison's disease to be most likely of tuberculous origin, but at the same time admits that there does not exist any specific treatment for this affliction and that tuberculin injections are useless. Tuberculosis of the pituitary body he believes to be of relatively rare occurrence but states that the toxin created by the tubercle bacilli is often responsible for symptoms which may be ascribed to a disturbed function of the hypophysis. Among the curative measures for intestinal peritoneal tuberculosis it is surprising to miss the heliotherapy and phototherapy which, in the hands of the American specialists, have given such satisfactory results in these afflictions.

To the student of surgical tuberculosis the chapter on orthopedic therapy in this volume will be interesting although I question that any of the methods described are superior to those in vogue in our best orthopedic American hospitals in which röntgenotherapy in tuberculosis of bones and joints is resorted to, quite a good deal. It is surprising that heliotherapy has received no mention whatsoever in this book in spite of the wonderful results which are obtained in bone and joint tuberculosis by Rollier and his disciples.

Of interest is the chapter on chemotherapy in tuberculosis, that is to say, chemical substances to which are ascribed indirect influences on the tuberculous process. Here are mentioned calcium silicate, arsenic, gold and copper preparations, creosote and chaulmoogra oil. Regarding the value of all of these substances, I wish to translate as nearly as possible the concluding words of this chapter written by Prof. Loewenstein himself, which read: "Concerning all these preparations, ye may say that at any rate we do not as yet stand on a sound foundation and much more research is necessary before we may even say we are working in the right direction."

The concluding chapters take up the treatment of tuberculosis at home of adults and children and give prescriptions for the symptomatic treatment of tuberculosis. Some statistical considerations of tuberculosis in tropical regions make an interesting finale of a very large, highly interesting and instructive volume—too large for the perusal by the general practitioner, but invaluable for the specialist and the student of the tuberculosis problem in all its phases.

THE EYE IN PULMONARY TUBERCULOSIS

Inégalité Pupillaire et Tuberculose Pulmonaire. By Dr. W. Jullien. Paris: Amédée Legrand, 1923. Pp. 117.

The author of this book, upon the suggestion of Prof. E. Rist, of Paris, made a thorough study of the value of the inequality and dilatation of the pupils as a diagnostic means in pulmonary tuberculosis and also to see if it might be a possible guide in the performance of artificial pneumothorax. The frequent dilatation of the pupils in pulmonary tuberculosis on the affected and sometimes on the opposite side, has of course been observed for years, but only recently has it been affirmed that this sign might be a guide as to which side presents the pleuritic adhesion, and whether or not and to what extent artificial pneumothorax may be practical. The dilatation of the pupils is explained by pressure arising from tubercles or adhesions on the branches of the sympathetic nerve.

The author precedes his arguments and clinical proofs by a chapter on the innervation of the iris and then proceeds to interpret the many physiological causes which may be responsible for the inequality of the pupils. He also gives a modus operandi of the various means to bring about a temporary dilatation or contraction of the pupils and a method of measuring the inequality, if it exists. Lastly, photographs are reproduced of the eyes of a number of tuberculous patients, showing the pupils and at the same time giving the x ray photographs of the chests.

His conclusions, based upon the careful observation and study of seventy cases in the Laennec Hospital and the Leon Bourgeois dispensary in Paris, are as follows: An inequality was found in twenty-six per cent. of the cases of unilateral tuberculosis; it was also shown that apical lesions are not always productive of a dilatation of one of the pupils, and it is hardly ever found when the lesions are near the hilus or at the base of the lungs. The study of other cases has also shown that in nontuberculous affections attacking the parenchyma of the lung, such as bronchiectasis when accompanied by sclerotic tissue, in cases of neoplasms, hydatid cysts, and even in gangrene of the base of the lung, dilatation of the pupils has been observed. This very careful study shows the relatively small value of the dilatation of the pupil as a diagnostic means in pulmonary tuberculosis. Jullien's work will nevertheless always remain an interesting contribution to our knowledge of the subject.

MENTAL DISORDERS

Mind and Medicine. By Thomas W. Salmon, M.D., New York: Columbia University Press, 1924. Pp. 33.

A few pages have been found in such an attractive and durable form that they should carry their message throughout the medical profession. The author has presented a challenge to his fellow professors and his students, in the address reproduced here, which is no less a matter for thought everywhere. Medicine, he states with just pride, has made marvelous advance in investigation of the organic basis of disease. Nevertheless, it has been so carried away with the fascination and the value of these discoveries that it seriously neglects the far more widespread functional problems which lie in mental disorders and in the social disabilities which follow. Medicine, for the greater part, has gone brilliantly on its way, turning a cold shoulder to this field, the pressing problems of which have proved themselves in need of medical understanding and aid most of all. Salmon points out what has been done by the few who have turned their earnest attention in this direction, and that this is only indicative of all that still remains for the more determined undertaking of the medical profession. It is not a matter for a few special groups; it has been that too long. The mental phenomena are inescapable phenomena in the field of every practitioner and should be within every curriculum, if any and every patient is to be known and treated in his total reactions, if, in fact, the physician is to consider either himself or his patient in the total of the social environment.

HUMAN CONSTITUTION

The Human Constitution. A Consideration of Its Relationship to Disease. By George Draper, M.D. With 208 Illustrations and 105 Tables. Philadelphia and London: W. B. Saunders Company, 1924. Pp. 345.

The practical application of anthropological data as found in the individual in relation to his tendency to certain diseases is the object of this study. The work is a worthy one and Draper has done much to lay a workable foundation. This work is only a bare outline of what may be filled in by future workers. Data of this kind should be more sought after especially in hospitals and other large public institutions. Not only is there value in it from the viewpoint of medicine but there should also be gained data of infinite value to the study of genetics, longevity, and heredity. Draper has displayed originality in working out certain formulas and their relationships. The work is a commendable one.

PATHOLOGY

Lectures on Pathology. By Ludwig Aschoff, M.D. Delivered in the United States, 1924. With Thirty-five Illustrations. New York: Paul B. Hoeber, Inc., 1924.

These lectures, delivered in various parts of the country before medical associations, colleges, and academies, in the spring of this year, range in subject from the concept of inflammation to atherosclerosis, thrombosis, and the origin of gallstones. Naturally, their reading is, as some one said of the dictionary, most interesting but slightly disconnected. Aschoff has an open mind and, of course, a well informed one, on the subject of endocrinology and, for this reason among many others, the perusal of his Lane lectures (San Francisco) on the normal and pathological morphology of the suprarenals, and that on ovulation and menstruation is recommended to some of our doubting Thomases who refuse to admit that a thing exists until it is thoroughly explained. One of the most instructive lectures is a review, in the light of the most recent investigations, of renal secretion and renal diseases.

ACQUIRED CHARACTERISTICS

The Inheritance of Acquired Characteristics. By Paul Kammerer. Translated by A. Paul Maerker-Branden. Illustrated. New York: Boni and Liveright, 1924.

Kammerer states his case and to many biologists proves it. Others in defense of certain pet theories find this difficult. The reader of this book will find much to think about for Kammerer is not finished with a proof of his theories, he goes on and applies them forensically, materially and individually. No matter what opinion the reader may hold he should find much to inspire individual thought.

CHOREA

Les Chorées. Par Dr. Babonneix. Bibliothèque des Connaissance medicales, dirigée par le Docteur Appart. Avec 34 figures dans le texte. Paris: Ernest Flammarion, 1924.

This small book should be of value to the neurologist. Babonneix has done a great deal of careful work on the choreas. If he offers little that is new at least he has organized the various choreas in a sequential manner. Of principal value is the setting forth of the differential diagnostic, and the underlying pathological conditions found in Sydenham's, Huntington's and other choreas and choreiform movements.

THE OLD TESTAMENT

The Literature of the Old Testament in Its Historical Development. By Julius Bewer. New York: Columbia University Press, 1924. Pp. 452.

This work of Bewer's edited by Shotwell is a real contribution. A reading of this carefully compiled series of analytical researches will animate the Old Testament and by so doing will give the reader an historical concept of the material which it contains. In this way the Old Testament becomes an epic gathered from the songs, poems, narratives, fables, proverbs, oracles, laws and other primitive fire cords. The work has been done with meticulous care and in the eyes of the reviewer serves a more useful function than would the work as the author first planned it. The anthropologist as well as the student of human endeavor with its attendant problems will welcome this volume. It is a good companion to Frazer's work on the Old Testament.

THE BAINBRIDGE FAMILY

Yesterdays. By Lucy Seaman Bainbridge. Illustrated. New York & Chicago: Fleming H. Revell Co., 1924.

In writing and publishing this little book, the author has benefited and given a document of special interest not to her grandchildren alone, as was her purpose, but to the members of the medical profession, to whom the name of "the boy," William Seaman Bainbridge, stands high on the list of surgeons of this country and of American physicians who have held important official positions in the United States and as representatives of the country abroad. Dr. Bainbridge was sent as delegate from the United States to the *Congres International de Médecine et de Pharmacie Militaire* held in Brussels in 1921 and also to the meeting of the *Comité Permanent* in 1922. Interest in things foreign and far afield was, it seems, a traditional characteristic of his mother's family. "The love of home and desire for travel seemed always in conflict," writes Mrs. Bainbridge, who was herself a great traveler, as those know who have read her books, *'Round the World Letters* and *Jewels from the Orient.*

"'The little house says "stay":
The little road says "go."'"

Her father, "the boy's" grandfather, was of Quaker origin, and maintained throughout his life the utmost simplicity and principles of the highest integrity. He was one of the founders of the firm of Seaman & Smith, leading boot and shoe manufacturers of Cleveland, Ohio.

His wife, in days when it was considered a discredit to a woman to study medicine, entered the field and graduated as a physician. When the Western Homeopathic College in Cleveland finally, after much opposition, consented to admit her to lectures, she was put by herself in the gallery with an armchair and a footstool; "but many a friendly smile was sent up to her from below, and she was called the 'guardian angel.' She made the most of their good fellowship and invited the class often to bountiful suppers at her home. . . ." When she began to practise, she set aside in her home "the Lord's Room," which was nearly always occupied by a patient, a poor student, or someone in sorrow. It was largely through her zeal and influence that the first woman's medical college was organized in Ohio, and she was its first president. During the second year of its existence, the Seaman Free Dispensary was established, and occupied a room in the college building under the control of the faculty. No wonder that her daughter, Lucy, visiting in Washington in 1864, and hearing of the need for nurses at the front—there were no trained nurses in those days—went there at once. "There was no pretty nurse's cap or white uniform to wear, but just plain, everyday clothes—a gingham dress and apron; no dainty and becoming white veil with a red cross over my forehead or on my arm. My distinguishing mark was simply a badge of red silk pinned on my left breast, on which were printed in gilt the words 'Ohio Relief.' Thus I went down the Potomac . . . At Port Royal on the Rappahannock, White House Landing on the Pamunkey, and, finally, at City Point, I had experiences of war which memory will never lose. How much was accomplished is a problem for the arithmetic of eternity." A night when Clara Barton visited the camp and shared "Sister Ohio's" big blanket shawl and log pillow, glimpses of Lincoln and Grant at the front, and other wartime episodes are described with a simplicity and vividness that testify to Mrs. Bainbridge's unusual ability as a writer. A delicious sense of humor is always present, from the time when the little red headed girl "got back" at the boys who had teased her about her fiery hair, to the last page of the book, describing a visit to Dublin, where three statues adorn the Post Office. These are pointed out to the tourist as the Twelve Apostles. "But where are the other nine?" is the natural question. And the answer: "Inside sorting the mail."

The comments on places and people encountered during the trip 'round the world made by Mrs. Bainbridge and her young son are delightful, and full of unusual and interesting bits of information, such as that of the village in China that was suffering from a drought. The inhabitants were dragging an idol through the streets, raising a terrible cloud of dust as they progressed. "Now," they were telling the idol, "that your eyes are full of dust, you can know how it is with us."

PLAGUE YEARS

Fortune's Fool. By Rafael Sabatini. Boston: Houghton, Mifflin & Company, 1923.

A simple enough tale of the exigencies of living and loving in London during the great plague. It has its picturesque moments, and by novelty the heroine rides in a sedan chair! Randall Holles, toughened veteran of many wars whose sword service is not desired by his country—Sylvia Farquaharson, the reigning state favorite, virtuous even in those days of the stage's disrepute, greater and lesser lights in England at the time of the war with the Low Countries,—all flit through the pages of Sabatini's romance, easily and gracefully. In due time we shall see them on the screen. And ere long perhaps we shall meet them again, against another historic setting, in another crisis, tearing out their hearts with the same old, ever-new fervor that "gets" the public. Harmless and amusing—true to life—perhaps! At any rate a faithful mirror of the favorite types foisted upon well meaning authors by clamorous audiences.

Medicoliterary Notes.

Lea & Febiger, the well known publishers of medical works, have recently moved into their new building on South Washington Square, Philadephia. The completion of this building marks the one hundred and fortieth year of the firm's existence, for it was established in 1785, antedating the Constitution of the United States by four years, and has been in continuous operation ever since. One of the founders of the firm was the recipient of an unsolicited check from Lafayette to aid in the establishment of the business. In its earlier days, Lea & Febiger published, among other notable works, Wemyss's biographies of Washington and Marion, Jefferson's *Notes on Virginia,* and American editions of the Waverley novels, Dickens, Washington Irving, Fenimore Cooper, and the *Encyclopaedia Americana.* Later it began specializing in medical works and has since continued in this field. For sixty-six years it has been the publisher in this country of *Gray's Anatomy,* and of the *American Journal of the Medical Sciences* since 1820. For many years Lea and Febiger were the publishers of the *Medical News,* which was incorporated with the NEW YORK MEDICAL JOURNAL in 1906.

Everlasting Life: A Creed and a Speculation, is the title of a little book written by Dr. W. W. Keen and recently published by Lippincott. It is a brief but vivid story of how Dr. Keen passed through an anxious period of doubt and distress and emerged into "a broader, happier, sunny belief in the goodness, mercy and love of God, into a real, glorious belief in the Atonement by our Divine Lord and Savior Jesus Christ, who was 'Son of God' and also 'Son of Man!' Hence this little book with this glorious Christian Magna Charta."

* * *

In the *National Geographic Magazine* for November, Major Robert Whitney Imbrie has an interesting article on *Crossing Asia Minor, the Country of the New Turkish Republic.* He writes: "If your digestion and nerves will not stand almost continual coffee drinking—the thick, black, syrupy coffee of the Orient—and endless cigarette smoking, venture not into the Near East. No business is ever transacted, no social call is complete, no meeting, however casual, is ever terminated without tobacco and coffee. One must be prepared to drink at least one dozen, and perhaps two dozen cups of coffee a day and consume many cigarettes if he is to get along on this trip. Of course, if one can smoke the nargile, or Turkish pipe, so much the better, but if he can, he is a better man than I am. Twice have I essayed to master this quaint instrument, and on both occasions interest was not all I lost. It leaves a feeling as if one had been smitten with what the newspapers describe as 'a dull, blunt instrument.'"

* * *

Because of the many inquiries received at the New York quarantine station as to the importation of dead bodies, a statement of the general requirements governing the intrastate and interstate transportation of such bodies has been prepared in Washington, and published in *Public Health Reports* for October 31st.

* * *

Because of temperature expansion and contraction, the Washington Monument, it has been estimated, is about five and a half inches higher in summer than in winter.

* * *

The American Relief administration has recently issued a bulletin carrying the detailed account of the distribution of the food remittance packages in Russia, of the relief measures for the nation's brain workers, and the resultant earning of funds for feeding three million children.

* * *

The first volume of Gabrielle d'Annunzio's three volume autobiography, entitled *Le Faville del Maglio,* is out. This volume is called *Il Venturiero senza Ventura,* and contains a spectacular dedication to Eleonora Duse, whose love was the inspiration of the writer's art. The page following the title page bears the inscription: "I am what I am by the grace of God."

* * *

The *Nation's Health* for November contains an interesting article on the *Maintenance of Interior Lighting Systems.* Experience indicates, it is stated, that often more than thirty per cent. of the light paid for goes to waste through inattention to maintenance requirements.

* * *

One of the recent publications of the Yale University Press is *Organic Adaptation to Environment,* edited by Malcolm R. Thorpe. It comprises papers on the subject by eight authorities.

* * *

In the Manhattan section of New York there have been more than one hundred deaths in a single year due to falls on stairs. The total number of such fatalities in the United States is estimated to be about 14,800 each year. The majority of these falls are due either to slipping or tripping, the former being far more prevalent. About eighty-five per cent. of accident on stairs occur during December, January and February. This is due to snow, ice and poor lighting.—*Nation's Health.*

The one hundred and twenty-fifth anniversary of the birth of Alexander Pushkin, greatest of the poets of Russia, is being celebrated in that country.

* * *

Dr. Mikkel Hindhede, a Danish nutrition expert, has recently added another book on improper food and eating habits as the leading cause of cancer's increased death rate. He warns against overeating and rich foods.

* * *

"Books," the *Herald Tribune's* literary supplement for October 26th, contains a review of unusual interest of Dr. Paul W. Harrison's recent book, *The Arab at Home.* "The author's twelve years in Arabia have led him to the conviction that the one thing men want is equality. He has put his finger on the sore spot of the world."

* * *

An exhibit of six thousand specimens of insects and related organisms which exert disease producing action on human beings and animals is on display in the Vienna Museum of Natural History. The entire life cycle, as far as is known, of each specimen is given. Those wishing to study the collection are furnished with expert guidance for a week. The exhibit is divided into groups according to the method in which the insects produce the various diseases —whether by means of gland secretion, by hairs, by poisonous appendages, by bloodsucking, or by transmission of disease germs.

The first Turkish novel to appear in English has recently been published by Duffield & Company of New York. It is entitled *The Shirt of Flame* and the author is Halide Edib Hanum, who was the first Turkish graduate from the American School for Girls at Constantinople. The scene is laid at the time of the Revolution, and there are vivid descriptions of battles and hospital scenes, but the book is perhaps most valuable as expressing the point of view of the Turkish "new woman."

Abstracts from Current Literature

TUBERCULOSIS

Calcium Metabolism in the Tuberculous.—M. P. Weil (*La Médecine,* May, 1924) states that the decalcification known to exist in tuberculosis through analysis of the tissues and experimental investigations is due rather to reduction of the power of the tissues to fix calcium than to insufficient ingestion of calcium salts. The percentage of calcium in different foods and in the waters in different localities varies enormously. Vegetable foods are rich and meats poor in calcium. Elimination of calcium takes place through the bowel, kidneys and mammary secretion. The greater the amount of alkalies in the diet the greater the ratio of calcium elimination through the bowel as compared to that through the kidneys, insoluble calcium salts—phosphates and carbonates—forming more readily in the bowel under these conditions. If the diet is acid, on the other hand, soluble calcium compounds are formed which are easily absorbed by the bowel and eliminated through the kidneys. Renal elimination of calcium also increases with the amount of acid secretion in the alimentary tract. Calciuria, often an inherited condition, is, as a rule, merely an expression of phosphaturia, due to exaggerated conversion of insoluble dicalcium to soluble monocalcium phosphate. Urinary decalcification is often merely an outward evidence of dephosphatization. An adult on a vegetable diet, without water, milk or eggs, takes in at least 0.15 gram of calcium a day, whereas a milk diet may result in the ingestion of as much as seven or eight grams. Growing individuals require much calcium, but adults need only 0.2 to 0.5 gram in calcium oxide. Insolubility of calcium salts is not an absolute bar to their absorption, but absorption is much better if the calcium is taken in organic compounds, as in vegetables and milk. A colloidal condition of the calcium, as in fresh plants, seems powerfully to favor its assimilation. The insufficiency of calcium fixation in disorders attended with decalcification is related to an insufficiency of certain necessary sensitizing agents, viz., the internal secretions, vitamines and light. The effect of adrenalin in osteomalacia is well known, and Sergent lays stress on the conjoint use of adrenalin with lime salts in the tuberculous. The gonads, thyroid, thymus, and perhaps in particular the parathyroids, also exert a considerable influence. The fat soluble vitamine A has an extremely marked fixing property in relation to calcium; this applies to codliver oil, which is especially rich in vitamine A. Light, especially sunlight and the ultraviolet rays, has a similar property. A normal subject, sufficiently exposed to light, with properly balanced internal secretions and receiving a diet of normal vitamine content, will thrive on the simplest mineral calcium compounds and consequently even more so on the semiorganic lime supplied in the ordinary diet. On the other hand, an impoverished, debilitated body, living under poor hygienic conditions, should be given the lime it lacks, in order to reduce to a minimum its work of assimilation.

Typhoid Activity and Tuberculosis.—E. Coulaud (*La Médecine,* May, 1924) notes that certain clinicians, struck by the fact that goitre cases showed a special resistance to tuberculous infection, concluded that thyroid activity antagonized such infection and advocated the administration of thyroid extract or iodine in tuberculosis. As a matter of fact, however, the size of the thyroid gland is not an index of its functional activity. Hamburger and Betz observed that the development of goitre during tuberculosis was a prognostically favorable occurrence and also noted frequent tuberculous flareups after treatment of goitres with iodine or by surgical means. The author, among large families living under poor hygienic conditions, has repeatedly found seven or eight cases of tuberculosis out of about thirty individuals belonging to three generations; the goitrous subjects, even though often sleeping in the same bed with tuberculous sisters, were always free of tuberculosis. Hypothyroid and myxedematous individuals exhibit a resistance to the disease. The problem is more complex as regards the relationship of true exophthalmic goitre to tuberculosis, as tuberculosis appears to be uncommon in such cases. The explanation offered is that true exophthalmic goitre is a dysthyroidia, which may actually coexist with myxedema. In the less advanced, incomplete Basedow syndrome, however, pulmonary tuberculosis is rather commonly met with. The periods of physiological thyroid overactivity in the female, viz., puberty, menstruation, delayed menses, pregnancy, and the menopause, are critical periods in respect to tuberculosis, Ingestion of thyroid extract aggravates active tuberculosis, and the author has seen many patients in whom tuberculosis appeared after prolonged ingestion of thyroid. Pathology confirms these views in that the thyroid gland in tuberculous cases is generally found in good condition and free of fibrous change. Rabbits in which the thyroid has been exposed to the x rays sufficiently to cause a lasting deterioration of the gland prove more resistant to tuberculosis than controls, in spite of the deleterious effect of the rays on the body as a whole, evidenced by loss of weight after each exposure. To eliminate this factor the author experimented with the offspring of rabbits in which the thyroid had been exposed to the x rays. In such litters the thyroid gland shows modifications easily recognizable histologically. Whereas the controls succumbed to tuberculosis in three months, some of the animals of the special litters showed little evidence of the disease at the end of a year. Cordier observed that a rise of basal metabolism in tuberculous cases was prognostically unfavorable. Jacquerod, giving goitre extracts to tuberculous cases, observed rather favorable effects, whereas the ordinary thyroid extracts are distinctly harmful.

Tuberculosis of the Bronchial Glands in Infancy.—E. Wieland (*Schweizerische medizinische Wochenschrift,* February 21 and 28, 1924) asserts that the clinical symptomatology frequently is of no avail in the early stages, nor is röntgenology always a reliable diagnostic aid. In addition to perfect exposures with soft tubes, it also requires free exposures in different directions in order to expose to view the lymph nodes at the bifurcation of the trachea, which are covered by the middle shadows. Any pathological shadow formation found must be differentiated from circumscribed tumors originating from other thoracic viscera and particularly from inflammatory, acute swellings of the lymph nodes occurring not infrequently after infectious diseases. However, the latter is possible only with the aid of the von Pirquet cutaneous test or of the intradermal tuberculin reaction. In general the prognosis is not unfavorable.

Organic Arsenic Compounds in Pulmonary Tuberculosis.—John Guy and G. B. Page (*Lancet,* April 26, 1924) endeavored to determine whether the modern organic preparations of arsenic offer any advantages over the older compounds, particularly in pulmonary tuberculosis. Novarsenabenzol was given intravenously in weekly doses of 0.3 or 0.45 gram up to six injections, the course being repeated after an interval of a month in some cases. Sulpharsenol was given intramuscularly in three different doses, the second proving the most useful, viz., a purely tonic course of six to eight injections weekly from 0.12 to 0.24 gram, a similar series of 0.30 gram after a smaller trial dose, and a course of biweekly injections such as might be used in treating syphilis.

The principal effects noted were those of the arsenic, but they were obtained more rapidly and in a more marked degree than in control cases treated with Fowler's solution added to an emulsion of codliver oil or with Blaud's pills with arsenious acid. After each dose there is an increasing tonic effect, a feeling of well being, sharper appetite, and returning strength. The improvement in the appearance, color, and weight of the patient is very marked. Anemia disappears more rapidly than under routine sanatorium treatment. The organic preparations of arsenic have no direct effect upon tubercle bacilli in any way comparable to their action upon spirochetes. The majority of patients showed an increasingly positive complement fixation reaction, but the significance of this is uncertain.

The types of cases suggested for this treatment are: 1, cases of extensive disease with some activity, where one would hesitate to use vaccines, but where there remains some prospect of producing arrest or extreme chronicity; 2,

ases which "hang fire" after a period of sanatorium treatnent; 3, cases in young adults with anemia, but otherwise avorable; the period of institutional treatment may be hortened thereby; 4, cases of double infection—syphilis and uberculosis; 5, as a therapeautic test in doubtful cases of ung disease. With simple precautions there is no risk; the nischief which may follow tuberculins cannot occur. The mprovement obtained is due to a general stimulation of the netabolic functions of the patient; there is no specific effect ipon the bacilli. Organic arsenic does not pretend to be anther new cure for tuberculosis.

Value of the Menstrual Reaction in the Determination of the Activity of Tuberculous Symptoms, Especially in the Lungs.—H. Maendl (*Wiener klinische Wochenschrift,* May 1, 1924) was enabled to obtain information regarding he activity and the extent of the tuberculous process through he lighting up of the tuberculous process in the lungs durng menstruation in seventy-seven per cent. of his cases. The occurrence of this phenomenon indicates a process that s active or likely to become active. He observed that auscultation during menstruation revealed dry râles at the pulmonary apices in women in whom no signs of apical catarrh was evident in the absence of menstruation. The author asserts that this test is an aid not only in the diagnosis, but it also indicates an active specific process.

Roentgenotherapy in Tuberculosis of the Bones and Joints.—Julius Hass (*Wiener klinische Wochenschrift,* May 1, 1924) states that roentgenotherapy promotes the production of cicatricial tissue and the inhibitive local powers. The amount and the nature of the irradiation are very important. The result is determined not by the hardness of he rays but by the amount of irradiation absorbed. There is no definite dose in tuberculosis and it must be gauged for the individual case. Excessive doses must be avoided. At first, it is well to begin with three skin unit doses (Holzknecht), which are then gradually increased until threshold focal reactions, such as increase of swelling and local increase of temperature, are produced. Only two thirds of he maximum dose should be given to avoid serious consequences. The author usually applies five skin unit doses hrough four mm. aluminum to every part in adults. Children require about one half to two thirds of this dose.

Tuberculin and Heliotherapy in Bone and Joint Tuberculosis.—W. A. Clark (*Journal of Bone and Joint Surgery,* October, 1923), draws the following conclusions from his three cases of bone and joint tuberculosis: In the three cases under tuberculin treatment the temperature was more regular and lower than it was before treatment was begun. Leucocytosis was stimulated in two of the three cases. No appreciable effect on the sinuses was noticed; these sinuses, however, were secondarily infected. Sunlight can penetrate he living tissues to some extent; this penetration is greater at higher altitudes than at sea level or intermediate levels. Direct sunlight inhibits the growth of tubercle bacillus. The course of the disease is shortened and the patient's general condition is better under heliotherapy than without it.

Direct Cultivation of Tubercle Bacilli from Spinal Fluids. Occurrence of Human and Bovine Types.—Ruth Gosling and John Montanus (*Journal of Experimental Medicine,* September, 1924) present data to show hat tubercle bacilli can be directly cultivated; that such ultivation is possible even when the number of tubercle acilli present is so small that they cannot be demonstrated n the direct smear of the centrifuged sediment; and their eries of cases cited shows the relative incidence of human nd bovine types in tuberculous meningitis, only three of orty-eight strains of tubercle bacilli isolated being of ovine origin. The sediments from thirty-four fluids were tudied, Dorset's and Lubenau's egg media being used or planting. Twenty-five of these thirty-four fluids, or 3.3 per cent., yielded positive cultures. The authors believe that direct planting of the sediment from cases of uspected tuberculous meningitis, where no organisms can e shown in smear, may have some value as a diagnostic rocedure, and that when guineapigs are used for the isolaion of strains of the tubercle bacillus from spinal fluids, specially when conditions are adverse to the proper care f the animals, due to overcrowding and incidence of epiootic diseases during the winter months, the planting of ome of the sediment directly upon egg media may be the neans of saving some strains for further study.

Treatment of Tuberculous Abscesses.—Siegfried Romich (*Wiener klinische Wochenschrift,* May 1, 1924), individualizes his treatment of tuberculous abscesses according to the stage of their development. Productive abscesses should be punctured repeatedly. The longer the formation of a fistula and the development of mixed infection is delayed, the firmer is the surrounding protective wall and the less dangerous is the infection. In the presence of mixed infection during the productive stage a wide incision is necessary. Cold abscesses require puncture, emptying of the pus and subsequent suture. With progressive healing and the formation of a firm membrane, the outlook for radical surgical intervention is improved, in which case a wide incision, the application of tincture of iodine and a compression bandage are indicated.

Overdiagnosis of Pulmonary Tuberculosis.—J. D. Adamson (*Canadian Medical Association Journal,* July, 1924), presents the following propositions. 1. Overdiagnosis is an evil, comparable in its results to underdiagnosis and correctly negating a diagnosis of tuberculosis though more disagreeable and more dangerous is as highly to be commended as is the finding of an early case. 2. Slight variations from what are conceived to be normal physical findings unsupported by posttussic crepitations, or xray shadows in the lung parenchyma are insufficient evidence of pulmonary tuberculosis even in the presence of general symptoms of debility and cough. 3. Occult tuberculosis, subliminal tuberculosis, peribronchial tuberculosis, *et hoc genus omne,* are not sufficiently proved to warrant their use as final diagnoses. 4. The presence or absence of localized, peripheral, parenchymatous shadows, in well taken xray films, is by far the most important point in making or breaking a diagnosis of early pulmonary tuberculosis. It is imperative that the clinician himself should have the facilities to search for and the training to recognize these radiographic changes.

Surgical Treatment of Tuberculosis.—H. Lilienthal (*American Journal of Surgery,* January, 1924), summarizes his findings as follows: 1. Surgery is not intended to supplant medicine in the treatment of tuberculosis of the lungs. It should be resorted to when medical and hygienic treatment have nothing more to offer and the patient's life is intolerable or the prognosis is grave. 2. Operation may have two distinct objects, first, the placing at rest of an entire lung and second, the obliteration of apical cavities. 3. Collapsing thoracoplasty, with phrenic nerve resection, puts the lungs at rest to a greater degree than is possible by any other known method. It is only to be applied when the other lung can function sufficiently to support life, and when it is not affected by rapidly developing tuberculosis. 4. Thoracoplasty does not take the place of therapeutic pneumothorax for no return of function is possible. In pneumothorax lung function can be restored, when desirable, in a large number of cases. 5. Arrest or great improvement following collapsing thoracoplasty may be expected in about seventy-five per cent of the cases. 6. The obliteration of apical cavities can be done on both sides of the chest. It is worth performing the operation when the disease in the remaining parts of one or both lungs is capable of arrest. 7. The operations here discussed are sufficiently safe to be recommended in properly selected cases. 8. The surgeon must never lose sight of the fact that although his wound may heal and his immediate objective be reached, his patient still has tuberculosis and will long require medical and hygienic treatment.

Treatment of Tuberculous Affections by Inflation with Oxygen.—The method recommended by Robert Purves and E. J. Bilcliffe (*British Medical Journal,* May 24, 1924), consists in evacuation of the abscess (by aspiration, trocar and cannula, or incision) followed by inflation by oxygen gas. The trocar and cannula are the best, but in deeply situated abscesses evacuation by free incision commends itself. Evacuation is frequently facilitated by changing the position of the patient. The apparatus required consists of oxygen in the usual cylinder, connected by tube to a wash bottle containing hydrogen peroxide; this is connected in turn by a tube to a hydraulic cannula, or to a Potain aspirator needle fitted with a two way tap which connects with the aspirator bottle and the suction syringe. A glass tubing containing a filter of sterile cotton wool is interposed midway. This with a coil of rubber tube on either side lies in hot water to warm the gas.

The aspirator or trocar should be introduced through sound skin, and if possible in such a manner as to produce a valvular closure on its withdrawal. If the abscess is evacuated by incision, the needle should be inserted at a distance from the incision after the cavity is evacuated. The incision is then closed in layers, if possible, before the gas is introduced. This procedure is contraindicated in the presence of sinuses or redness of the skin and of mixed infection. Tuberculous peritonitis with effusion has not shown good results. This treatment is easily carried out and can be given to ambulant patients. No unpleasant sequelæ have been seen.

Qualitative Variations of the Neutrophile Leucocytes in Pulmonary Tuberculosis.—Th. and J. Stephani-Montana (*Schweizerische medizinische Wochenschrift,* February 21, 1924) assert that the shape of the nuclei of the neutrophile leucocytes is significant in pulmonary tuberculosis. Comparative clinical and microscopical examinations show that those neutrophiles which show a rather extensive ramification of their nuclei prognosticate a favorable outcome, whereas those with more rounded nuclei indicate a more grave outcome.

Syphilis Simulating Tuberculosis.—George G. Ornstein (*Medical Clinics of North America,* July, 1924) states that hemoptysis, cough, expectoration, etc., are to be considered as caused by pulmonary tuberculosis until proved otherwise. The symptoms mentioned with negative röntgenographic and physical findings should suggest a possibility of syphilis. A positive Wassermann reaction or other stigmata of syphilis will corroborate such a diagnosis.

Tuberculosis of the Breast.—Nathan Raw (*British Medical Journal,* April 12, 1924), draws the following conclusions from a series of ten thousand cases: 1. Tuberculosis of the breast is always caused by the bovine bacillus. 2. It is never primary, but is the result of lymphatic extension from the glands of the neck or axilla (excepting in the rare cases of general miliary tuberculosis). 3. In common with all other forms of surgical tuberculosis caused by the bovine bacillus, it responds readily to treatment by a tubercle vaccine prepared from an attenuated culture of human tubercle bacilli. The treatment must, however, be continued for a long period until an active immunity is established.

Renal Tuberculosis.—R. A. McComb (*Canadian Practitioner,* April, 1924), gives these indications for nephrectomy: 1. Where one kidney is tuberculous, even with good function, and the other is not tuberculous and has a good function. 2. Where one kidney is much diseased causing a great deal of trouble with practically no function, and the other is slightly infected and doing all the work. Contraindications: 1, both kidneys tuberculous; 2, where the better kidney has a poor function; 3, active and advanced lesions elsewhere, especially in the lungs; 4, other constitutional conditions.

Severe Tuberculin Reactions, Scrofula, and Status Lymphaticus.—Charles McNeil (*British Journal of Children's Diseases,* October-December, 1923), concludes that in a small number of cases of tuberculous infection the tuberculin cutaneous reactions are unusually severe. In a majority of such cases of severe tuberculin reaction the type of lesion is that formerly described as scrofulous, and commonly includes a scrofulous or phlyctenular conjunctivitis. There is evidence that such cases of scrofula are associated with the condition known as status lymphaticus. The term scrofula should be retained as denoting those types of tuberculous infection which are associated with the morbid condition status lymphaticus, and which in consequence exhibit an intensified reaction to the tubercle bacillus and its poisons.

New Method of Treating Tuberculosis of the Upper Air Passages with Local Phototherapy.—Emil Wessely (*Wiener klinische Wochenschrift,* June 19, 1924) found that erythema is produced by irradiation with violet and ultraviolet light. With red light the extent of penetration is a few centimetres, but with ultraviolet light it is only the fractional part of a millimetre. Irradiation with the latter B rays are developed in the affected tissues, which exert a great chemical influence: they react upon tuberculous tissue just as destructively as sunlight. The best results are obtained with rays of one three hundred millionth of a wave length to one three hundred forty millionth of a wave length; this part of the spectrum is the best.

The aim of the treatment is to imitate sunlight and to apply the light to the tissues affected with a suitable apparatus. The simple arc light does not serve this purpose, but carbon impregnated with metal salts is very suitable and provides a light which closely simulates sunlight in the part of the spectrum mentioned. These carbons contain copper. The lamps used by the author have a quartz lens, as glass allows the penetration of only a small part of the short wave lengths. The amount of light that falls upon a certain area is greater than that emitted by the quartz lamp. This light gives only a local reaction and only irradiated ulcers heal. Forty-eight per cent. of the cases were affected favorably and twelve per cent. remained unaffected.

Efficacy of Direct Culture of Tubercle Bacilli from Infectious Material.—Ernst Löwenstein (*Wiener klinische Wochenschrift,* March 6, 1924), found that if five times the amount of a forty per cent. sulphuric acid or a thirty-five per cent. hydrochloric acid is added to a specimen of sputum, there is formed a voluminous sediment in which the tubercle bacilli may be found. With this technic all associated bacteria are destroyed and the tubercle bacilli may be cultivated on glycerin potato or egg albumin media in one hundred per cent of the cases. Organic acids, like acetic acid and lactic acid, do not destroy associated bacteria even in strengths of 50 per cent. Such a direct culture shows better results than the animal experiment. In some cases, in which the bacilli were not pathogenic for guineapigs, the bacilli were of the avian type. The latter have a marked affinity for the hemopoietic organs and occur with polycythemia and leucemia. The author was enabled to obtain a pure culture of the bacilli from sputum or wine even in cases in which the antiformin procedure failed to show a positive result.

PEDIATRICS

Wasting Disorders of Early Infancy.—Leonard G. Parsons (*Lancet,* May 10, 1924) draws the following conclusions: 1. That in many cases there is a great deal of evidence in support of the view that the onset of infantile atrophy is due primarily to the supply of insufficient and unsuitable food. 2. That however the initial loss of weight has been produced the continuance of the atrophic state depends upon an altered metabolism and not upon disorders of digestion and absorption. 3. That the rational treatment of pyloric stenosis of infants includes the performance of the Rammstedt operation at the earliest possible moment.

Acute Intussusception in Children.—W. A. Thompson (*British Medical Journal,* May 17, 1924) makes the following observations: 1. Eighty-eight per cent. of cases occurred in the first twelve months of life. 2. Sixty-two per cent. occurred between the fourth and the eighth month. 3. The ileocecal type only includes those cases where the intussusception apparently started at the ileocecal valve and where this remained as the apex. 4. The majority of cases started as ileocecal, in which the last portion to be reduced was the ileum. The commencement of the intussusception in the ileum was recognized as a well defined dimple. 5. The jejunal type of intussusception described in so many textbooks was not seen by the author. It is found postmortem in children dying from other diseases. It is probably of no pathological importance. 6. The ileocelic type was the most fatal. Perhaps this type may occur in those cases where the cecum is less mobile.

Mortality in the Surgical Diseases of Children.—George David Cutler (*Boston Medical and Surgical Journal* August 21, 1924) gives as the factors entering into mortality in these cases the nature of the disease or injury, its duration before surgical intervention, and the age of the patient. Analysis of the 261 mortalities in 8512 patients shows that about half the deaths resulted from infection, a quarter from congenital malformations. Delay is of importance, and the younger the patient the poorer the prognosis.

Mortality in the surgical diseases of children may be further reduced by prevention of infections, burns, trauma; earlier diagnosis of surgical conditions with immediate and appropriate treatment; attention to preoperative condition of the patient as regards dehydration, lack of blood, acidosis, improper feeding and correction of same.

Successful operations on children demand specially trained surgeons and attention to conservation of body heat, speed consistent with accuracy, careful hemostasis and gentle

manipulation of tissues. After operation supply heat, treat dehydration and acidosis as occasion arises. The use of breast milk is of great importance in feeding infants after operation. Transfusions, exsanguination transfusions and intravenous medication with mercurochrome or gentian violet offer some hope for reduction of mortality in severe infections. Dakin's solution irrigations are of great value in appropriate cases of localized sepsis. Intestinal drainage above obstructions perhaps with more two stage operations will lower the mortality from this condition. Only earlier recognition of tumors can contribute to a reduction in their operative mortality. It is doubtful if this will affect the end results. Postoperative treatment with xray or radium offers only a possible chance of cure. Spina bifida and hydrocephalus continue to be perplexing problems for the surgeon. The high mortality rate is only slightly reduced by surgical interference.

Hemorrhage of the Newborn.—Floyd Clarke (*Archives of Pediatrics,* May, 1924) summarizes his findings as follows: 1. Hemorrhage of the newborn is more frequent than the early literature would lead us to believe. 2. Blood coagulation and bleeding time tests should be done as a routine and thus possibly prevent some of the early deaths occurring in infancy. 3. More autopsies should be done and thereby assist in proving these facts and bringing them to more general notice. 4. Early surgical procedure and diagnosis may help in preventing some of these children from becoming hopelessly crippled and mentally deficient. 5. The injection of whole blood is curative in hemorrhagic disease of the newborn.

Malignant Tumors of Testicle in Children.—A. A. Kutzmann and T. E. Gibson (*Annals of Surgery,* December, 1923).

1. Malignant tumors of the testicle in children are comparatively rare.

2. These tumors are extremely malignant and of them, the teratoma, which is found mostly in early childhood, is the most malignant.

3. The prognosis of malignant tumors of the testicle in children is very grave.

4. The mortality rate is very high and has as yet been very little influenced by present methods of treatment.

5. The case reported is probably an embryonal carcinoma of the left testicle; that this tumor is highly malignant is evidenced by the local recurrence, the extensive metastases to the lungs, right lobe of the liver and retroperitoneal ymph nodes and by the invasion of the inferior vena cava.

Arsenic Dermatitis in a Child, Treated with Sodium Thiosulphate.—Charles R. Bugg and Caspar Folkoff (*Bulletin of the Johns Hopkins Hospital,* March, 1924) report a case of severe dermatitis in a child following the administration of arsenic. The patient received six injections at intervals of one week of 0.22 gm. sulpharsenol intramuscularly into the buttock. The patient manifested a marked eczematous and exfoliative type of dermatitis, which responded well to the intravenous injection of sodium thiosulphate. The drug was given in four graduated doses, a total of 1.35 gm. being sufficient to cause practically complete disappearance of the skin lesions in the course of six days.

Dyspepsia in Childhood.—C. E. Sundell (*Practitioner,* July, 1924) says: All are familiar with the child who "can't eat" this or that, or who "never eats a proper meal." What is required in many of these cases is treatment of the mother rather than of the child. Children live in a world of fancy, in which they are the centre and pivot, round which all their surroundings and experiences revolve; they have a constant desire to express their personality and to attract interest; what finer opportunity can they find for this than a tussle with authority at every recurring mealtime? The pleasure of eating is for these children negligible compared with the gratification of the sense of selfimportance by refusal to eat. The wise mother or nurse can appreciate this point of view, and by calm neglect of the point at issue can shatter the child's resistance. By the time we are consulted in these cases, coaxing, cajoling, threatening and punishment have all been tried, and too often the result has been complete failure. The best advice to give is that small portions of sound food should be provided; if these are refused no comment is to be made, but at the end of the mealtime the food is to be thrown away in the presence of the child. This plan is far more often successful than the alternative of serving up at a meal food discarded at a previous meal. In all cases it is essential that there should be no fuss, no apparent distress of mother or nurse, and, most important of all, no hint or mention of food refusal in the hearing of the child.

Fixed Principles in the Feeding of Infants.—F. M. Fry (*Canadian Medical Association Journal,* June, 1924) suggests the following general principles as suited for agreement. There is no one artificial food suitable to all infants (or all adults). Infants vary greatly in their idiosyncrasies, their toleration and digestion of food and even in their requirements. Patients, therefore, need to be studied and tested just as much as foods have been in the past, and a few days are well spent in testing a child's toleration. The food should be suited to the patient, not the patients to the food. Feeding must be, partly at least, empirical, for foods must be digestible and otherwise acceptable to each patient. Infants have a reserve, often, of digestion, which we cannot measure, and there may be several different but equally successful foods for a given case.

Human milk is still the best food for the human offspring, and therefore that artificial food, at least in normal cases, should be preferred which most resembles human milk. Caloric feeding, if rigidly followed, is often a farce, for a calorically correct food is by some infants refused, or vomited or discarded by the bowel, and children vary in their caloric requirements. The most accurate means of measuring quantities is by calories. Qualitative feeding (percentage feeding) alone is equally fallacious—both the qualitative balance and the caloric value should be considered.

It is wise to distinguish between feeding in the normal and feeding in the abnormal. In the former our rules will apply; in the latter our rules may fail us and empiricism must prevail. Proteid milk is a temporary therapeutic agent with a definite narrow indication. The chief value in proteid milk, in concentrated or in modified proteid milk, and in lactic acid milk, is in the lactic acid which inhibits all other bacterial activity and makes casein more digestible. It is not important (in most cases) to give any one sugar exclusively. Maltose is absorbed in larger proportion than other sugars, breaks up into two molecules of dextrose, and often quickly gives a striking gain in weight. It aggravates some cases of vomiting by being partly split up in the stomach, and is less laxative than other sugars, because it is absorbed higher up in the alimentary canal.

Critical Three Day Fever in Children (Exanthema Subitum).—This disease picture, previously described only by American authors, was also observed in Berne, Switzerland, by E. Glanzmann (*Schweizerische medizinische Wochenschrift,* June 26, 1924). It is characterized by a suddenly appearing and critically defervescing (after three days) high fever up to 40° to 45° C., followed simultaneously or after a few hours after the crisis by a scarlatinal or measles like rash, chiefly on the trunk and on the hairy parts of the head, which disappears after two days without any sequelæ. During the febrile stage the symptoms, in addition to unrest, anorexia, and headache, there may be no other or slight catarrhal symptoms. This disease affects chiefly infants at the age of six to twenty months. There seems to be no contagiousness. The striking and diagnostically and prognostically important features are the pronounced leucopenia with a marked relative lymphocytosis of eighty to ninety per cent., an increase of the large mononuclears and a diminished eosinophilia.

Effect of Fluid on the Temperature and Blood Concentration in the Newborn with Fever.—H. Hakwin, R. M. Morris and J. D. Southworth (*American Journal of Diseases of Children,* June, 1924) find that when fluid is given by mouth in the proportion of from thirty to forty c.c. to the kilogram of body weight a prompt fall in the temperature and blood concentration follows with great regularity. The temperature usually reaches normal within thirty to ninety minutes. When the fluid is given hypodermically or intraperitoneally, the effect on the temperature and blood concentration is neither so marked nor so regular as after water by mouth. Water by mouth, in amounts similar to those used in the newborn with fever, has practically no effect on the temperature of infants with fever due to various infections. In a group of older infants, dehydrated as a result of severe diarrhea, fluid by mouth is much more effective in reducing the concentration of the blood than fluid given hypodermically or intraperitoneally.

COLLISION WITH FURNITURE AS CAUSE OF MALIGNANT TUMOR

The Illinois Supreme Court, Ascher Bros. Amusement Enterprise v. Industrial Commission, 311 Ill., 258; 142 N. E., 488, affirmed an award for the death of a theatre usher from a malignant tumor alleged to have resulted from twice coming into collision with the end of a seat in the course of his duties. "His attending physician testified that in his opinion it was a traumatic sarcoma; that sarcoma is a malignant growth, a tumor which has a tendency to spread and an inherent tendency to destroy life; that in his opinion a person walking down a theatre aisle and bumping his knee against a seat would not ordinarily produce sarcoma, but it is very common, following even the slightest injuries. He testified that the death was primarily due to the sarcoma."

EXEMPTION OF CHARITABLE HOSPITALS FROM TAXATION

In a suit by the city of San Antonio and the San Antonio school district against the Santa Rosa Infirmary and the Sisters of Charity of the Incarnate Word for taxes, the sole defense was that the defendants were exempt under section 2, article 8, of the state Constitution and Revised Statutes, article 7507, exempting public charities from taxation. Reversing judgment for plaintiffs rendered by the Court of Appeals (249 S. W. 498) the Texas Commission of Appeals says that the constitutional requirement is twofold; the property must be owned by the organization claiming the exemption; it must be exclusively used by the organization, as distinguished from a partial use by it, and a partial use by others, whether the others pay rent or not. It was held the hospital was exclusively used by its owners as a general hospital, though the major part of the rooms were used for pay patients, although surgeons, not themselves wholly engaged in a charitable work, were permitted to use the operating rooms for certain fixed charges imposed upon their patients able to pay, although a certain ward was devoted to the charitable work of a clinic conducted by the Sisters of Charity, and although the dispensary in the building sold drugs to its pay patients for a profit. The state Constitution does not in terms require a charitable institution, if it may claim exemption from taxation, to use its buildings exclusively for charitable purposes, as it does require in the case of educational institutions that they be used exclusively for educational purposes, but the requirement is only that the buildings be used by the charitable institution as above pointed out. Both the clinic and the drug store were operated by the owners of the hospital.

Such a charitable institution, it is held, to be exempt from taxation, need not be founded exclusively upon gratuities or donations, and does not lose its exempt status because it goes in debt for its plant and pays that debt and the interest accruing on it out of its incidental earnings.—Santa Rosa Infirmary v. San Antonio (Tex.), 259 S. W. 926.

KANSAS COURT'S DEFINITION OF IMMEDIATE AND CONTINUOUS

In an action on an accident policy the evidence tended to show that the plaintiff, in going to the telephone in the night, injured his great toe by striking it against the furniture with such force as to drive the nail into the flesh, resulting in the nail having to be removed. For about ten days plaintiff was unable to conduct his business; for the next ten days he was able to perform his office work, when what proved to be a pyogenic infection developed, requiring him to go to the hospital, where he remained for some time and was operated on several times. The insurer contended that plaintiff was not continuously disabled longer than the first ten days after the accident; and that any loss of time after that was not covered by the policy. The policy had a rider indemnifying for injury by pyogenic infection resulting from an accident. The evidence was that the pyogenic germs, or pus creating germs, do not develop at once from the injury, but require time in the natural course of events for their development. An injury develops at once, it is held, within the meaning of a policy of this character, when it follows directly from the accidental hurt within such time as the processes of nature consume in bringing the person affected to a state of total incapacity to prosecute every kind of business pertaining to his occupation. Hence the fact that it took ten days or more for the injury to develop in its ordinary course to such an extent that plaintiff was wholly incapacitated from performing any of his duties did not prevent the injury from being immediate and continuous within the meaning of the policy. Rabin v. Central Business Men's Assn., Kansas Supreme Court, 226 Pac., 764.

ELECTION OF REMEDIES BY SETTLEMENT OF SUIT FOR MALPRACTICE

In an action against physicians for damages for breach of an agreement by which the defendants were alleged to have agreed for a consideration to cure the disease from which the plaintiff was suffering, the pleadings disclosed that for the alleged injuries received in the treatment the plaintiff had a right to proceed against the defendants either in an action in tort or an action ex contractu for the breach of an agreement, and that he had elected to sue the defendants in tort for malpractice, which suit was settled for $2,000. The Alabama Supreme Court, Knowles v. Dark & Boswell, 99 So. 312, holds that the same act constituted both a breach of the contract and a tort, and that the plaintiff's election of remedies by suing in tort and receiving compensation in that action precluded his recovery for breach of the contract.

COUNTY'S LIABILITY TO PHYSICIAN FOR PROFESSIONAL SERVICES TO POOR

The Kansas Supreme Court holds, Leinbach v. Board of Comrs. of Pottawatomie County, 226 Pac. 993, that an unintentional failure of a claimant to verify his account against the county for medical services performed at the instance of an overseer of the poor is not a justifiable ground for the rejection of the claim.

Assuming the truth of the facts alleged and admitted—that the plaintiff, a physician, at the instance of the township trustee as overseer of the poor of the township, rendered medical services to a moneyless and friendless person lying dangerously ill in a third class city in a certain civil township over which the township trustee had jurisdiction—it was held that the county was liable for the reasonable value of the professional services so rendered by the physician.

MEDICAL TESTIMONY AS TO EFFECT OF INJURY ON PLAINTIFF'S ABILITY TO FOLLOW OCCUPATION HELD ADMISSIBLE

In an action for personal injuries consisting of a fractured skull, the Oklahoma Supreme Court holds, Marland Refining Co. v. McClung, 226 Pac. 312, that it was not error to permit a medical witness who had examined the plaintiff to state his opinion as to whether the injury would interfere with the plaintiff in following his occupation, which involved manual labor.

VOL. CXXI, No. 2 NEW YORK, WEDNESDAY, JANUARY 21, 1925 WHOLE No. 2297

American Surgery and the Surgery of the World

WELLER VAN HOOK, M.D.

Chicago

Those who wish to promote American surgery must know the nature of world surgery, and carefully appraise its rival activities and successes. To them must be sharply known the various countries and cities of the world where the problems pressing on us for solution are being most keenly studied. In their minds must rest knowledge of where are the present centres of practical clinical and research opportunities; of free, abundant and accurate publications; of the expansion of influence by contacts among students and teachers, and the very routes of commerce and travel that provide the advantage of interrelationship which vitalizes surgical enthusiasm and action.

One must distinguish between the insular and the cosmopolitan types of surgery. The latter are inclusive, general, productive, expansive; the former are contracted and barren—their successes are fitted for themselves alone, their failures are without even postmortem profit to anyone. In America one can make effort to keep in touch with and practise universal surgery; but it can be done only with great labor and a deep well springing of interest and enthusiasm.

There are four world divisions of surgery—the Teutonic, the Latin, the British and the American. The Scandinavians with their new and brilliant *Acta Scandinavica Chirurgica* are forging forward, under a heavy linguistic handicap, for a fifth division.

Each of these divisions is characterized by human temperamental and intellectual differences and by the possession of ethnical, linguistic, political and economic unities that invite or enforce common methods of action.

Let us glance for a moment at these world divisions of surgery. The Teutonic has the advantage of mass. The thoughtless often consider that crushed Germany, having no longer ample power to maintain her mechanism of universities and clinics, is not now much to be considered as a factor in surgery. This lapse of reasoning is a fatal error of generalship, for two great reasons. The first is that our German fellow scientists are full of activity and enthusiasm. Increased sickness due to national depression and the burden of the war-maimed have stirred the Teutonic profession to the heart. The German surgical congresses are strong and fairly well attended, although all continental surgeons find it difficult to obtain new books and periodicals, and research is greatly hampered. The second reason is that Germany has the intimate intellectual sympathy of all that part of Europe lying north, east and southeast of her. To this must be added the more or less intimate thought cooperation of Switzerland, of Italy, of Turkey and of Japan. The Scandinavian countries and Holland share the feeling of the other countries mentioned that surgical contributions of the first class ought to find at least secondary publication in the German language. These facts make it necessary for progressive surgeons to continue the study of German surgery even today. For Teutonic surgeons give the world now a larger, more varied, more piquant and substantial literature than does any other single group mentioned in our analysis.

The Latin division also has been stimulated by the war necessities and opportunities. Here France easily leads, and dominates the surgery of all the lands touching the Mediterranean Sea as well as all Latin America. If Paris were to gather, entertain and instruct the surgeons of all Romance language countries biennially her helpfulness and power would be infinitely greater. The Latin division of surgical literature needs more diligence, greater depth and thoughtfulness with a profounder basis of research. May material prosperity come to the aid of our French brethren.

British surgery, backed by the English speaking surgeons of all non-American countries is hopelessly John Bullish—God bless it. We have, all of us, the defects of our qualities. British surgeons of the highest ability sometimes give us epoch making contributions. But not enough British surgeons write; they have only one first class surgical journal; they do but little experimenting; they do not visit or sufficiently consider the vast jungle of the Continent of Europe, although they are beginning to notice America; and their books are usually *ipse dixit* affairs, disdaining the long, tedious, well chosen pages of literary references that are a joyous find for the man who writes the next article of the necessarily endless stream. It is typical of England that she discovered Lister abroad! British surgery grows and is helpful. We wish there was more of it.

Copyright, 1925, by A. R. Elliott Publishing Company.

The American division of surgery is waking up. The glories of its nineteenth century activity consisted in some brilliant isolated McDowells, Thomases, Emmetts, Grosses and the like, some of whom, laudably enough, peddled their ideas in Europe to gain recognition and renown.

What has given us the American surgery of our day? It was the influence of men like the Dane, Fenger, the Swiss, Senn, the Canadian, Osler, and the American, Halstead, who brought Continental European modes of scientific thought into our midst and who taught our young men to go to Europe for more of such cultural contacts.

No country can remain scientifically isolated and thrive in surgical thought. Two bits of service of the first quality have been recently performed for American surgery—first and most important, the attraction into our periodical literature of first quality original articles by surgeons from world remote lands; the other the cultivation of scientific friendship with Latin American surgeons.

American surgery seriously needs deeper scholarship and critical acumen. The scholarship we need is the larger scholarship that would give surgery its just setting amidst world intellectual culture; the criticism demanded would gently and firmly put to the forefront dignified and scholarly speech and writing, eschewing vulgarity of thought and wording. It would edit away colloquialisms of speech from dignified reviews; it would restore the memories of our surgical forefathers even if they knew not of asepsis. Especially would it enforce the grammatical and even the graceful use of language, driving back to its lair the admissible brutalities of the protocol. We must welcome the advent of unhasting surgical reviews. And especially must we avoid the insular study and citation of the work of others as presented in the English language alone. We must be of all the work, not of America alone.

Furthermore, let no American surgeon practise his art to suit the fashion of American congresses or, indeed, of any other isolated bodies. Let our ambition, for each of us, be to know the surgery of the whole world and choose, each for himself, the very best. Let us have no standardized surgery; let us have a progressive surgery, individual, keen, discriminating, lofty and conservatively bold.

American surgery can be great only by consorting with the surgery of the whole world, choosing the best and adding thereto its own profoundest thought.

31 North State Street.

Focal and General Infections*

Factors in the Production of the Acute Abdomen

J. O. BOWER, M.D., F.A.C.S.
Philadelphia

With the passing of typhoid fever and the occasional perforation of the bowel which accompanied it, the most frequently recognized acute surgical abdomen in the presence of a bacteriemia ceased to exist. It is interesting to note that probably the typhoid bacillus *per se* was not responsible for the perforation—at least cultures obtained from the peritoneal cavity and edges of the ulcer failed to show it, more frequently the colon bacillus and streptococcus were found.

The pneumococcus and the streptococcus invade the abdomen through the blood more frequently than any other microorganisms. In the pneumonias of children due to the pneumococcus, the peritoneum is attacked infrequently compared with the other serous cavities and is usually only seen by the surgeon when the patient is in extremis. This is also true of the peritonitis due to the streptococcus alone. The patient's chance for recovery is slight, as he is overwhelmed before the tissues are able to react. Dudgeon and Sargent (35) believe that the reason death takes place so rapidly in streptococcic peritonitis is due to the fact that the body cells are only slightly phagocytic.

The accepted treatment for these two conditions at the present time is primarily not surgical. To live, the patient must react vigorously. The best the surgeon can do is to recognize, institute Oschner treatment with the hope that the infection will localize. At times, however, a bacteriemia due to an attenuated type of pneumococcus, streptococcus or other microorganism occurs in which the secondary process localizes in the alimentary canal or its accessory organs. Whether this localization interferes with the normal functioning of the organ depends first upon the virulence and peculiar characteristics of the infecting organism, and secondly, upon the resistance of the patient. Likewise, its recognition will depend upon the organ affected, the relation it bears to the digestion and the extent of the pathology. If the lesion is small it may heal without leaving any evidence of previous involvement so far as symptoms and signs are concerned and frequently microscopic examination of sections of the supposedly diseased organ fails to show the pathology suspected. An example of this remarkable reparative process was recently observed by me: a perforation had occurred in the centre of an indurated ulcer, two cm. in diameter on the anterior wall of the first portion of the duodenum; the opening was closed by simple inversion; the patient recovered and returned two months later for excision of the ulcer; at operation no evidence of the former pathology could be seen or felt and a careful inspection of the mucous membrane of the duodenum failed to reveal any evidence of the former condition. A chronically diseased appendix probably accounted

*From the Surgical Department, Samaritan Hospital, Philadelphia, Pa. Read before the American Therapeutic Society, Toronto, Canada, June 6, 1924.

for the digestive symptoms which antedated the second operation.

The associated lesion in this case is not an uncommon finding at operation and at times accounts for the absence of pathology in tissue removed and explains, in many instances, the frequency with which symptoms and signs indicating a disease of one organ may be actually due to lesions in more than one or in the one least suspected. While these associated lesions found at operation are usually chronic in type, there is evidence that acute lesions occur concomitantly in the appendix, duodenum and stomach. The work done by Lansdonne and Williamson (23) is interesting in this respect. They found that in the substance of the mucous membrane of the intestinal tract are small round cell aggregates more or less distinct from the lymphoid follicles and that these appear "to suffer some general enlargement or destruction in appendicitis, gastric or duodenal ulcer and certain forms of dyspepsia." In a study of thirty-three patients dying as a consequence of septic appendicitis, the follicles in other parts of the gastrointestinal tract not infrequently showed equally definite evidence of attack. Microscopic ulceration and scarring of the gastric mucous membrane, ulcers at the base of the crypt's of Lieberkuhn, particularly in the jejunum and occasionally in the lower part of the large intestine and upper rectum occurred. These authors are of the opinion that the conditions mentioned originated as a result of some noxious agent, the nature of which has not been absolutely determined.

Studies made of diseased appendices from patients who came to operation for other conditions disclose the fact that a certain percentage are removed, in which the etiological factor is difficult to explain. Williamson and Slater (24) report the histological examination of five hundred appendices at the Boston City Hospital on the Gynecological Service. Of this number one hundred and sixty-seven were abnormal; sixty-four could be traced as secondary to pelvic inflammation, leaving one hundred and three abnormal appendices without signs and symptoms of disease. In other words, there were changes in the appendix without known cause and without apparent harm to the patient. No case diagnosed as appendicitis was admitted to the report.

It is within the realm of possibility that these lesions of the appendix, symptomless and without known cause, may have been but part of a general inflammatory process with local manifestations involving lymphoid tissue elsewhere. Murphy (34) has demonstrated the physiological relationship that exists between lymphoid tissue in the various parts of the body. I have seen lymph nodes in the axilla disappear as if by magic upon the application of radium to the cervical nodes in pseudoleucemia. Histologically we know that the younger the patient the more cellular is the lymphoid tissue. This is just as true of the tonsil as it is of the appendix and Lansdonne and Williamson (23) have shown that the lymphoid aggregates mentioned usually disappear from all situations after the age of forty.

The fact that in children appendicitis is rarely diagnosed as such, primarily, is not wholly due to the age of the patient, since the real condition is often obscured by a systemic reaction to infection that seems to be general in its scope and while it is not unusual to find septic appendicitis directly preceded by attacks of tonsillitis or exanthema in juveniles, in the adult it is rare. The following is a case report of an adult male, who developed appendicitis during the height of an attack of streptococcic tonsillitis:

Case.—Patient, male, aged thirty-seven, abdominal pain and sore throat developed thirty hours before admission to the hospital. Physical examination disclosed swollen tonsils covered with a grayish white membrane, and a rigid right lower abdomen. Temperature 103°, pulse 100, respirations 20. Leucocyte count 21,800; polymorphonuclears 85 per cent. A diagnosis of tonsillitis complicated with appendicitis was made. Operation under intraspinal anesthesia disclosed a perforated gangrenous appendix with general suppurative peritonitis. Culture from tonsils showed streptococci; from the appendix streptococci, coliform bacilli and diplococci. Blood culture negative. Patient discharged from the hospital on the sixteenth day.

Deaver (25) reports Kietz (26) as having seen two cases of appendicitis following tonsillitis. In one case streptococci were obtained from both the appendix and the tonsils, and in the other he recovered streptococci from the tonsils. In these instances the route of infection is usually by way of the blood stream. Dudgeon and Mitchner (27) made blood cultures from twenty-five patients suffering with acute appendicitis and found short chained nonhemolytic streptococcus in one case and a massive growth of a similar streptococcus was obtained from the interior of the appendix, which was gangrenous. Rosenow (28) believes that localization of the streptococci in the gastrointestinal tract is due to its peculiar qualities. He found that cultures of Streptococcus viridans obtained from patients suffering from severe gastrointestinal influenza produced lesions in guineapigs similar to those noted in patients.

Appendicitis accompanying or following an attack of influenza was not uncommon, especially during the worldwide epidemic. Potter (29) reports a case, Smith (30) reports another and Behrend (31) reports eight cases. He operated upon three of these patients and calls attention to the fact that the patients had been in bed four days before the symptoms of appendicitis developed. Whether it is due to the direct action of the infecting microorganism on the mucosa of the appendix, or to defective drainage on account of the swelling of the appendicular orifice is not known. In any instance the complication should be suspected in the average case of intestinal influenza in which the following symptoms and signs present themselves:

Persistent lower abdominal pain associated with tenesmus.
Localized tenderness.
Dullness in the flanks.
Increasing leucocytosis.

The symptoms of the true gastrointestinal type of influenza are, according to Rosenow, due in part to an anaphylactoid reaction which accounts for the difficulty in diagnosing the intraabdominal complications. Diarrhea is usually not an accompaniment of appendicitis and this in itself is misleading, espe-

cially if assocated with rectal tenesmus. In addition, the albuminuria of acute nephritis, which is not infrequently associated, may lead one to believe that the leucocytosis is due to a pyelonephritis. One should rely for the most part on the presence of localized tenderness, but even here the reaction of the peritoneum to stimuli seems to be diminished, the abdomen at no time presenting a semblance of rigidity commensurate with the degree of peritoneal involvement. A vaginal or rectal examination is helpful in arriving at a correct diagnosis. We recommend the use of spinal anesthesia in the acute abdomen in the presence of respiratory or nephritic complications.

Case II.—C. S., male, aged fifteen. Myalgia, cephelalgia and pharyngitis developed three days before admission to hospital. Diarrhea and tenesmus became marked; on second and third days patient said he had a hundred bowel movements. No nausea or vomiting. On admission, abdomen was slightly distended, no rigidity, slight tenderness in right lower quadrant, percussion tenderness over both kidneys. Urine showed heavy cloud of albumin, many red blood cells, leucocytes, granular casts and bacteria. Leucocyte count 11,000, polymorphonuclears 78 per cent. Operation under intraspinal anesthesia. Appendix nine cm. in length. Perforated two cm. from tip; distal three cm. gangrenous. On the twelfth day following operation, a subphrenic abscess was opened and drained; on the thirty-sixth day, abdominal wounds were closed following sterilization. Discharged from hospital on the forty-eighth day.

PERFORATED DUODENAL ULCER

In 1912 I reviewed the case histories and visited personally twenty-eight patients who had been operated upon for perforation of the duodenum by Dr. Babcock and his associates prior to that date. Since that time about twenty patients have been operated upon for the same condition. With one exception, the perforations occurred in males, who were, in ninety per cent. of the cases, suffering from gingivitis, pyorrhea and dental defects of marked degree. It was my opinion at that time and I still believe that focal oral infection is responsible for the majority of these perforations. It is true that in most instances cultures taken from the site of perforation fail to show organisms, but one must remember that the acid gastric juice may interfere with the growth. It has been repeatedly demonstrated that cultures taken from the edge of the ulcer show a greater percentage of positive findings than those from the peritoneal exudate. Wilensky (36) believes "that the perforation through the base of an old ulcer is an embolic phenomenon occurring during the course of some temporary bacteriemia, the evidence of which may be so transitory as to be undemonstrable."

Mutch (33), in a bacterial study of the intestinal content of those suffering from infections of the teeth, gums, tonsils, nose and pharynx, is of the opinion that from the centres of saprophytic growth in the chyme of the ileocecal region long chained cocci invaded the mucous membrane and so opened up new channels for their dissemination in the tissue, where they continued life as parasites. They frequently spread upward, invading the jejunum and sometimes the duodenum. Dudgeon and Sargent isolated streptodiplococci from the edge of perforated gastric ulcers in every case and from the peritoneal exudate in four instances out of a total of seven. It appeared as a diplococcus and also in chains of eight or ten cocci or diplococci. It was gram negative and a twenty-four hours' broth culture injected intraperitoneally failed to kill guinea-pigs.

In perforated duodenal ulcer the bacteriology is somewhat different. In most instances the exudate is sterile but the edges of the ulcer may contain staphylococcus, occasionally the streptodiplococcus or the colon bacillus.

ETIOLOGY OF ACUTE PANCREATITIS

From the standpoint of etiology, diagnosis and treatment, the relationship that diseases of the gallbladder and ducts bear to acute pancreatitis is of the utmost importance.

When Fitz (1), in 1889, published his paper on acute pancreatitis, he did not appreciate apparently that there is any pathological relationship between infections of the biliary tract and the pancreas. He calls attention to the rarity with which jaundice is associated with the disease, but no mention is made of biliary disease having been found at operation or post mortem in the sixteen cases he reported.

In 1901, when Opie (2) reported a case of acute hemorrhagic pancreatitis in which a small gallstone had lodged at the orifice of the diverticulum of Vater, so that it had converted the common bile duct and the duct of Wirsung into a continuous closed channel allowing neither bile nor pancreatic juice to escape, an interest in the relationship between the two conditions was stimulated. In 1903, he collected nine cases of acute hemorrhagic pancreatitis in each of which a calculus had been lodged near the termination of the bile duct.

Von Mikulicz (3), in 1903, thought that acute and chronic pancreatitis often followed cholelithiasis and cholangitis. Robson and Moynihan (4), in 1903, were of the opinion that "the essential and immediate cause of the various forms of pancreatitis is bacterial infection." In their opinion gallstones need not be present to produce the lesion. Mayo, Robson and Cammidge (5) quote Williams, Busch and Egdahl, who found that gallstones were present in forty per cent. of the cases of acute pancreatitis. Musser (6) in 1909 reported nine cases of acute pancreatitis with a history of gallbladder disease in seven.

In 1910, Opie (2) states that "no relation between hemorrhagic necrosis of the pancreas and bacterial invasion from the intestine has been demonstrated."

Korte (7) in 1912 reported forty-four cases of acute pancreatitis: twenty-one had cholelithiasis and one an infectious cholecystitis. J. E. Sweet (10), 1915, believes that the etiological factor in acute pancreatitis is the activation of the trypsinogen into trypsin, and that the liberation of the trypsin takes place by infection or trauma; infection taking place by way of the lymphatics.

Deaver and his coworkers, while being in accord with Sweet, differ somewhat in their opinion regarding the exciting cause. Deaver and Pfeiffer

(8), Deaver (12), Deaver and Sweet (15), believe infection takes place through the lymph channels; on the other hand, Deaver and Ashhurst (16) and Deaver and Remian (18) are of the opinion that the retrojection of bile as described by Archibald is a reasonable theory.

Moynihan (9), 1915, states that "the onset of the acute inflammation is due, in many cases, to the blocking of the ampulla of Vater by a small stone." Judd (11), 1916, agrees with Sweet. Archibald (14), 1919, believes that necrosis of the pancreas is the direct result of the action of substances entering the duct of Wirsung. D. F. Jones (19), 1920, reports forty-two cases. He believes the inflammation is due to retrojection of bile into the duct of Wirsung or duodenal contents into the duct of Santorini.

Undoubtedly the essential factor in acute pancreatitis is the activation of trypsinogen into trypsin. Whether the captivating agent is chemical and reaches the pancreas through the ducts of Wirsung or Santorini or whether it is an infection and passes by way of the lymphatics has not been absolutely determined. It is highly probable that both occur. From a review of the case histories, we can safely state that fifty per cent. of the cases had cholelithiasis. The exact percentage of patients who had cholecystitis will never be known. If we are to accept Judd's statement (20) that "we (the Mayos) were unable to recognize all cases of cholelithiasis with the abdomen opened," or Willy Meyer (21), "a glistening, bluish, soft and nonadherent gallbladder found during operation may be diseased and harbor pathological organisms within its walls," we can appreciate that many gallbladders have been reported normal in connection with acute pancreatitis that must have been diseased. Graham and Peterman (22) believe that in the majority of cases a cholelithiasis is produced secondary to a hepatitis by lymphatic extension. "By the direct injection of organisms (streptococci or staphylococci) into a radicle of the portal vein, as for example, the appendix vein, it is possible to produce cholecystitis almost as a routine." Might not the latter observation explain those cases of hemorrhagic necrosis without apparent etiology?

DIAGNOSIS OF PANCREATITIS

If one half of the patients in whom acute pancreatitis develop have gallstones and a fair percentage of the remaining half have hepatitis, choledochitis, or cholecystitis, a careful history will, in the majority of instances, lead one to suspect the previous involvement of the biliary system. Too much stress can not be laid upon the importance of a careful clinical history. In my opinion this is much more important from the viewpoint of diagnosis of uncomplicated biliary infection than physical examination, x ray findings, examination of the contents of the stomach, or even that obtained from the duodenum or biliary apparatus. Undoubtedly in a great many cases it will be impossible for us to determine by any means at our disposal at the present time that this infection is present in its incipiency, but a time will come when we will be able to accomplish this. Are not the complaints referable to the gastrointestinal tract which the patient brings to us and which we are wont to call qualitative dyspepsia due in part to a hepatitis which precedes or accompanies cholecystitis or pancreatitis?

The attack of acute pancreatitis is frequently ushered in with symptoms and signs not more severe than those which accompany the typical attack of gallstone colic. No doubt the pancreas is involved in a fair percentage of patients who have severe attacks of gallstone colic. Experimentally we know that the pancreas can take care of a considerable degree of necrosis. Bower and Clark (37), fifty mg. of radium screened with one mm. of brass were placed against the pancreas for twenty-four hours. Eleven days later a partial pancreatectomy was done. The dog died in an emaciated condition December, 1922, almost eight months after insertion of radium. At autopsy no remnants of pancreas were found.

The severity of the initial signs and symptoms of involvement of the pancreas *per se* depends upon the degree of the initial involvement. If the changes in the structure of the gland have produced an effusion with marked increase of pressure so that the capsule becomes tense, the pain becomes unbearable, the usual dose of morphia having no effect whatever; the location and type of pain differ from that of the average gallstone case in that it is more marked toward the midline and more constant; occasionally the pain may radiate to the right scapula or left loin. Associated with the pain is a marked shock; frequently this is so severe that the patient is rendered unconscious; more frequently semiconscious; the pulse becoming rapid and weak; the temperature subnormal; the lips and nose cyanotic; be a conspicuous symptom. It is usually accompanied by severe retching, the ejected fluid consisting of the contents of the stomach and then a bile stained mucus, at times containing blood. Physical examination of the abdomen shows it to be moderately distended, breathing being for the most part thoracic, a moderate amount of free fluid is usually present in the flanks and liver dulness is diminished. The upper abdomen shows an increased tension, more marked on the right and toward the mid line. Occasionally the entire epigastrium may be tense. Usually marked rigidity is not present. Perpendicular percussion on deep inspiration over a tense gallbladder elicits pain which is pathognomonic. Jaundice is rarely present.

DIFFERENTIAL DIAGNOSIS

Perforated duodenal ulcer.—The adult male between twenty-five and forty-five years of age, usually with a history of having indulged freely in alcohol, with previous symptoms of pylorospasm or hunger pain and food ease, who is suddenly seized with epigastric pain, severe enough to double him up; who does not usually vomit unless he takes something by mouth; who has a subnormal temperature and is in a peculiar type of shock in which the pulse is of fair volume and usually not over eighty-eight or ninety; who, on physical examination shows a rigid abdomen with a right rectus which stands out prominently; a diminution of liver dulness which gradually increases and perhaps shifting dulness in the abdomen, presents a typical case of perforation of the duodenum.

Biliary colic.—The diagnosis in the average case is usually made from the clinical history; when com-

plicated with empyema, hydrops, or stone in the ducts, the diagnosis with the aid of a physical examination becomes easier because the gallbladder enlargement can usually be determined in the former conditions, even in the obese. The biliary colic is associated with certain types of cholecystitis is more difficult to recognize but can usually be made by excluding pylorospasm caused by duodenal or gastric ulcer or chronic appendicitis.

Acute appendicitis.—An inflammation of this organ sufficient to produce an acute abdomen that resembles acute pancreatitis is not common; however, patients are brought to the hospital with this diagnosis. They are usually younger, (although Dr. Babcock has had a case of pancreatitis in a girl of fourteen years). The onset is not as sudden; it is not associated with shock; the pain is less severe; vomiting is not so persistent and not accompanied by severe retching; the temperature is higher; perpendicular percussion point tenderness is present; rectal and vaginal examinations invariably clinch the diagnosis.

Renal colic.—In one of the cases reported this diagnosis was made by the attending physcian. The pain, while being primarily in the upper right abdomen, was referred to the right lumbar region. The peculiar shock associated with pancreatitis is practically never seen in kidney colic. The vomiting is less persistent. Lumbar percussion tenderness is present and microscopic examination of the urine is usually sufficient to make a correct diagnosis.

Acute dilatation of the stomach.—Usually this occurs during or after operation. I, however, have seen one case following a stenosed pylorus due to the swallowing of a bichloride tablet. Usually the pain is not as severe, while shock and upper abdominal distention are more pronounced. Vomiting is not associated with the severe retching and the vomitus is more frequently composed of altered blood. The passage of a stomach tube makes the diagnosis evident.

Intestinal obstruction.—Except in some cases of intussusception, intestinal obstruction is not accompanied with the acute, severe symptoms that characterize acute pancreatitis. The pain and shock are less severe, the vomiting is of the overflow and not the retching type; the distention is usually not upper abdominal; early tenderness is not marked; visible peristalsis can frequently be seen, obstipation and subnormal temperature are invariably present.

TREATMENT OF ACUTE PANCREATITIS

Operative interference for relief of pressure, a decompression, as it were, of the compressed pancreas, is immediately indicated and just as early relief of pressure of the compressed brain in certain types of cranial injuries is essential to recovery, so it is with the pancreas. The analogy is quite obvious; both are enclosed in close fitting capsules; both have the power to absorb a large percentage of their own weight of fluid, which, up to a certain point, is a protective mechanism. Recent investigations seem to prove that the poisonous products are in the early stages confined to the capsule of the pancreas (the fluid that is thrown into the peritoneal cavity is not toxic as proved by the experiments of Whipple and Goodpasture (32). See Bower and Clark (37).

If Nature's protective mechanism neutralizes the toxic ferments thrown into the peritoneal cavity, it would seem that during certain stages of the disease, harmful effects would result from an incision into the capsule or into the glandular structure, permitting the escape of poisonous products which might overwhelm the patient. Probably this stage is that of acute hemorrhagic inflammation; in the later stages, those of gangrene and suppuration, we see the end products of the action of the pancreatic ferments on pancreatic tissue, and this, logically, requires different treatment.

This seems to be borne out by investigating the different series of cases reported by various authors. In Korte's series of forty-four cases, there are thirty-four operations: twenty-two, or nearly sixty-five per cent., were operated upon after seven days had elapsed; twelve during the first seven days. He states that necrosis may occur as early as the third or fourth day, so practically all his cases were in the stage of gangrene or suppuration when treated and incision with multiple puncture of the gland as advised and practised by him would be indicated.

Referring again to the cases collected by Robson and Moynihan in 1903, we find that similar treatment was employed in sixteen of the twenty-eight cases reported, with one recovery. The gallbladder was not touched in any of the operations. The average time from the onset of symptoms to operations was eight days; the shortest, one; the longest, thirty days. One patient recovered thirty days after operation.

In contrast to the above, is the series of operations reported by Deaver, seventeen in all, in which cholecystostomy was done on eleven cases with three deaths. He does not give the average time between the onset of symptoms and operation in this series but it seems to prove that cholecystostomy does cure acute pancreatitis and it must do it by relieving tension on the pancreas. The operation not only relieves tension by lessening the intraductal and therefore intraglandular pressure but also provides for the escape of infectious or obnoxious substances through the lymph channels. (Sweet (38)).

Thus we see that there is a tendency to do less to the pancreas. Deaver states, "We do not practise free and indiscriminate incision into the swollen pancreas because of the difficulty of controlling the free hemorrhage that is likely to result."

Jones advises drainage of the fatty capsule and the pancreas itself, in addition if the condition of the patient will permit, either the sphincter of Oddi may be cut, a choledocostomy or cholecystostomy done. Archibald advises cholecystostomy with prolonged drainage, from three to twelve weeks. He advises against drainage of the pancreas by incisions through its capsule, believing that one cannot drain a diffuse necrosis.

Four cases of acute hemorrhagic pancreatitis have come under my observation at the Samaritan Hospital, Philadelphia, all of which had gallstone disease and all recovered from a simple cholecystostomy. Two of these cases came under my care. The following is a brief abstract:

Case III.—Mrs. M. C. (referred by Dr. L. O. Davis), aged forty-two, entered the Samaritan Hospital with a history of having had frequent attacks

of indigestion during the past year. Present illness began eighteen hours before admission to the hospital, with excruciating pain in right hypochondriac and lumbar regions. This increased in severity and she stated that she fainted six hours later, being unconscious for ten minutes. Shortly after, she had a chill; nausea and vomiting were marked. Pain twelve hours later became localized to upper right quadrant. Her family physician gave her a quarter grain of morphine hypodermically, this gave relief for a short time only, a second being necessary. Vomiting continued until admission.

The physical examination was negative except for abdomen which was scaphoid; generally rigid right upper most marked. Free fluid could be elicited in the flanks; liver dullness diminished; pulse 120; respiration 36; temperature subnormal; urine showed trace of albumen.

The preoperative diagnosis was acute pancreatitis. Operation under spinal anesthesia; vertical right rectus incision. There was about 600 c.c. of dirty bile stained fluid in the peritoneal cavity. The upper origin of the mesentery was infiltrated with a hemorrhagic exudate. The head of the pancreas was tense and hard. The gallbladder was one and one half times its normal size, distended and contained several small calculi; one at the junction of the cystic and common duct. A cholecystostomy was done, using a dressed tube; a cigarette drain was placed below the gallbladder. This was removed on the fourth day and the dressed tube on the fourteenth day following operation; the sinus closed on the twenty-second day. Two years after operation the patient was in excellent health.

CASE IV.—H. D., male, aged forty-nine, policeman (referred by Dr. A. D. Kurtz). Was admitted to the hospital with a diagnosis of an acute abdomen; seven years previously he had an attack of upper abdominal pain; following this qualitative dyspepsia developed. Eighteen hours before admission severe epigastric pain developed. He took a laxative without relief. There was no vomiting. Twelve hours later pain became intolerable and he became semiconscious. He called the family physician, who gave him a hypodermic injection of one quarter gr. morphine without relief. The physical examination was negative except for the abdomen, which was moderately distended; the upper right quadrant tense and tender; percussion tenderness marked over the gallbladder. The preoperative diagnosis was gallstone disease. Operation under spinal anesthesia; modified Bevan incision; peritoneal cavity contained about 500 c.c. dirty fluid, areas of fat necrosis studded the gastrocolic omentum, while the mesentery at its origin, the peritoneum covering the second and third portions of the duodenum and parts of the gastrohepatic and transverse mesocolon were the seat of hemorrhagic infiltration. The head and neck of the pancreas were swollen and likewise infiltrated. The gallbladder was twice its normal size, grayish in color, nonadherent, and contained 556 gallstones, from three to six mm. in diameter. The bile was greenish black in color and ropy in consistency. A cholecystostomy, using a dressed tube, was done; a large cigarette drain was placed over the head of the pancreas. This was removed on the fourth day; dressed tube on twelfth, and patient was discharged from the hospital on the sixteenth day. Later there developed an incisional hernia and the patient was operated on at another hospital. The gallbladder and pancreas were of normal appearance.

CONCLUSIONS

1. The acute surgical abdomen is at times a concomitant of general and focal infection.

2. Tonsillitis, influenza and oral infections frequently precede or are associated with acute appendiceal and duodenal lesions.

3. Advanced, moderate or incipient pathology of the biliary systems precede the acute pancreatic lesion, so that a careful history will usually elicit symptoms suggesting a focal infection in the biliary passages.

4. Acute hemorrhagic pancreatitis should be thought of as a possibility in the acute upper abdomen. The management of the case depends entirely on the stage in which the patient is seen. In the acute hemorrhagic stage in which a few hours have elapsed between onset of symptoms and operations, a simple cholecystostomy is sufficient to relieve pressure and effect a cure. When the disease has progressed to the stage of gangrene and suppuration, opening of the capsule and drainage of the pancreas, with cholecystostomy are indicated.

A Familial Myopathy

ALFRED A. ROBINSON, M.D.
San Francisco

Interesting controversy marks the study of muscular atrophies. A search for definite morphological changes as the basis of their pathology has not been rewarded by completely clarifying the nomenclature of the myopathies.

Muscular atrophy is meant to designate a wasting of the muscles in which there are found pathological changes in the nervous system as the cause of the atrophy. By muscular dystrophy is meant a type of wasting with no discoverable lesion of the spinal cord.

The first observation on muscular atrophy was recorded in 1709 by Van Swieten. Later, Charles Bell described progressive muscular atrophy and in 1850 Aran and Duchenne placed this as a nosological entity. Duchenne believed this to be a disease primarily of the muscles. Cruvelhier, soon after, studied cord sections and stated the cause of the disease lay in the spinal cord. After much investigation with an improved histological technic, Charcot concurred in Cruvelhier's findings. He declared that the large multipolar ganglion cells of the anterior horns were the trophic centres of voluntary muscles and that pathological changes were present in muscular atrophy. Duchenne and also Erb accepted Charcot's interpretation. Friedrich, however, opposed their view and set forth that in a constitutional diathesis, weakening the muscular system's resistance, extreme exertions produce atrophy. He chose to call the condition polymyositis chronica progressiva and charged that Charcot's findings in the anterior horn cells were secondary to muscle deterioration.

Erb, in 1882, after personal study of numerous cases, declared that there were two distinct types of progressive muscular atrophy—a spinal atrophic form and a muscular dystrophic form, differing greatly in localization, syndrome and evolution.

In spite of Charcot's preeminence as a neurologist, he and his followers assented to Erb's differentiation. "In the course of time, all observers, Charcot and Marie included, agreed to accept the classification of Erb's" (1).

1. Dystrophia muscularis progressiva infantum
   - A. Hypertrophic form
     1. With pseudohypertrophy
     2. With true hypertrophy
   - B. Atrophic form
     1. With primary facial involvement (Duchenne's infantile form)
     2. Without facial involvement (simple atrophic form)
2. Dystrophia muscularis progressiva juvenum et adultorum (juvenile form).

Timmie (1) reports a family in which in several generations there is exhibited at times one of these groups and at other times another group. He states this is quite characteristic in the familial hereditary forms.

Recently, Leri, Girot and Basch (2) in a systematic study of seven cases of muscular dystrophy, "known also as idiopathic muscular atrophy," suggest that the line between muscular dystrophy and the spinal muscular atrophies should not be drawn too closely. They point out that muscular dystrophy is not strictly confined to the muscular system as there are frequently bony changes such as deformities of the skull and thorax, kyphoscoliosis and fragilitas ossium. Fibrillary twitchings and reactions of degeneration have been observed. In dystrophy, loss of tendon reflexes with preservation of muscles concerned has been noted. In such cases a nervous lesion must exist. However, in explanation of a Babinski toe reflex, Sicard (3) expressed the opinion that it is not necessarily a central nervous lesion as it may be due to relative weakness of the flexors, making extensor response easier when the foot is irritated.

In 1909 I observed a rather unusual type of body deformity, which, upon investigation, proved to be a familial myopathy. A search of medical literature failed to supply a description of this particular type. These cases now have been studied clinically over a period of fourteen years. Cord or muscle sections for morbid histology have not been available. In view of the fact, however, that certain prophylactic measures may save these patients extensive wasting, it would seem that this report is not premature.

DEFINITION

Familial myopathy is a hereditary, selflimited muscular dystrophy, appearing generally about puberty, affecting the muscles of the shoulders and arms, augmented by fatigue, toxemias and pregnancy; characterized by slow muscle wasting, producing a distinctive deformity and limited, awkward movements. It does not extend to other parts of the body nor decrease longevity. I believe this to be a disease *sui generis*.

ETIOLOGY

(Geographical distribution). The disease was first discovered in the wife of a pioneer who had left North Carolina in 1849. These people settled in the Mountain States but the family is now distributed in Utah, Idaho, Montana, California, Nevada, Washington and Oregon. It has been impossible to ascertain if the disease exists in other members of the family in the South.

Sex seems to play no important rôle. Of sixty-four per cent. afflicted, there were sixty-five per cent. of the males and sixty-three per cent. of the females affected.

These children are sound at birth and in childhood. About puberty there begins to appear so-called angel wing scapulæ. It develops at a later age in the male than in the female, in about the ratio that the female matures earlier than the male. This would seem to favor the contention of Timmie (1), that muscle atrophy is an endocrine disease, there being a change in the endocrine glands at this time of life.

Two children under observation for twelve years began to show the disease slightly at the ages of six and eight years. Even then there was little change until puberty and at that time of life the

ondition became pronounced. The father of these hildren, however, is a paretic and the mother is fflicted with the deformity.

Occupation had a decided effect on these victims. f the work is one that produces fatigue or excesive exercise of the muscles of the shoulders and

Fig. 1.—Note "finned" scapula, advanced position of heads of huneri, bare sternoclavicular junction and small right arm from use of violin bow, and hollow chest.

rms, the atrophy is greatly increased over a labor n which these muscles are allowed to rest.

The first case under observation, in 1909, was hat of a young man at the age of sixteen years. His nxious mother had watched his shoulders from irth, and now noticed the appearance of the winged capulæ. She was desirous that he be spared this ffliction, thinking, naturally, that if he chose a abor that would exercise the muscles of the shoulers and arms, these muscles would be enlarged and trengthened by such work. He studied violin and ecame an accomplished violinist—at the sacrifice of is shoulders and right arm. His right arm, with which he uses the bow, has now become so atrophic hat he is in danger of having to give up his profession. (Fig. 1.)

Occupation affects these cases in proportion to he overwork and fatigue breaking down the muscles, nstead of the normal enlargement under the stimuus of necessity.

In three cases where the disease had passed into a quiescent stage, the patients became the victims of nfectious diseases. Within three months after an ttack of typhoid fever, the deformity of one young nan was much increased. Another man, age twentyix, was able to do ordinary farm labor until he uffered from an attack of influenza in 1918. Since hat time he has been compelled to give up his work nd run a little candy shop, owing to increased weakess in the arms and shoulders. In a female patient Fig. 7) there developed marked atrophy of the latisimus dorsi following influenza. Her deformity was he usual one until this was added.

From these observations it would seem that toxnes of infectious diseases increase muscle wasting where the disease appears to be quiescent, either by action upon the anterior horn cells or directly upon the muscle fibres.

It is known to this family that pregnancy will bring on or increase the severity of deformity. From personal observation, one new case has developed and one woman made worse by pregnancy.

The deposit of adipose tissue tends to pad the shoulders and arms, and while it does not restore any of the reduced functions, the deformity is less apparent, with the exception of the advanced position of the heads of the humeri. The patient in Fig. 7 a few years ago, showed marked winged scapulæ and typical shoulder wasting but an increase in weight has served to improve her appearance.

The disease is decidedly an hereditary one. It is transmitted to about sixty-four per cent. of the children who reach maturity of those who are themselves afflicted. Members of the family who escape the disease do not transmit it.

Dr. C. H. Danforth, professor of anatomy, Stanford University, a research student of heredity, supplies the following discussion on heredity as an etiological factor:

The theory of heredity which has received the most general support assumes that the characteristics of the individual are primarily determined by discrete morphological entities in the germplasm. These are called genes. The individual is the product of interactions between these genes, and between them and environmental factors. The genes reproduce themselves with each cell division and are thus distributed to the tissues of all parts of the body. In development and in adult function it is the gene complex of the constituent cells which primarily determines the normal reactions of the tissues. With reproduction the maturation divisions result in germ cells with half the somatic number of genes. The genes, like the chromosomes in which they lie, are segregated in an orderly manner so that in the mature egg or sperm each gene is different from every other. At fertilization homologous genes are brought together in pairs and distributed essentially

Fig. 2.—Same patient as Fig. 1.

Fig. 3.—Lordosis posture.

in duplicate to the cells of the developing embryo. Within the same race the members of each pair are for the most part alike, but occasionally the homologous genes are not strictly identical. The result of such a condition may be a blend between the tendencies of the two opposing genes with a result-

FIG. 4. — "Finned" scapula. Same patient as Fig. 3.

FIG. 5.—Daughter of patient in Fig. 4, one year after puberty; normal before.

ing condition intermediate between those of the two parents, or one gene may act as a dominant entirely suppressing the normal effect of its mate. When such a dominant gene tends to produce some anomalous condition of structure or function this condition will appear in the individual who receives the gene from either of his parents and, on the average, in half of his children—since in reduction division half of his germ cells will get this gene and half will get its normal mate. Consequently the theory demands that when a single dominant trait is involved the typical family history will show that the defect appears in about half the children of each affected parent but in none of the children of normal members of the family.

E. G.: Suppose A B C D . . . . represent the individual genes and suppose a modification of A, call it A′, produces muscular atrophy. Then an individual with the disease will have the formula: A A′ B B C C D D . . . . When the cells divide in growth each of these genes will divide so that each of the two new cells will have the original formula; but in the formation of germ cells the well known reduction division process will separate the genes into two classes thus:

— AA′ —	Synopsis	— A)	(A′ —	
— BB —	and	— B)	(B —	
— CC —	metathose	— C)	(C —	Final
— DD —	stages	— D)	(D —	division
— ′ ′				
— ′ ′				

So the formula for the two kinds of germ cells will be A B C D . . . . and A′ B C D . . . . In other words, they are alike except for the one point, whether they contain A or A′. The chances that any given egg or sperm cell will contain A or A′ are even. Now if the affected individual marries a normal husband or wife all of the latter's germ cells will contain A B C D, etc., but no A′. Consequently when fertilization occurs there is an even chance that the germ cells involved will be A B C D . . . . A B C D . . . . or they will be A′ B C D . . . . + A′ B C D. This means that on the average half the children will be A A B B C C D D E E and half A A′ B B C C D D E E . . . . The former obviously should be unable to transmit the trait, the latter, identical with the affected parent, should do so.[1]

In the study of twenty families, extending over five generations, there was a total of 128 children. Of these 128 children whose parents were affected, in eighty-two the disease developed—sixty-four per cent. There were forty-nine males and seventy-nine females in all. Of the forty-nine males, thirty-two were affected, or sixty-five plus per cent., and of the seventy-nine females there were fifty affected, or sixty-three plus per cent.

These figures do not cover children under puberty or those who died before attaining that period.

[1]Original contribution.

PATHOLOGY

In the study of this disease no cases have come to autopsy. Also, it has been impossible to secure section of muscle from living subjects. It is natural to suppose there are degenerative changes in the anterior horn cells. Just whether this would be primary, producing atrophic disturbances in the muscles, or secondary to peripheral disease, is an unsettled question to the writer.

FIG. 7.—Daughter of patient in Fig. 6.

FIG. 6.—Atrophy extended to upper arm.

Wassermann reactions were negative in nineteen cases examined. It is not a luetic affliction.

X ray in nine cases failed to give any information. Study of the head in region of the base, clinoid processes and sella turcica revealed nothing. The value of pineal shadow is doubted. The scapulæ and heads of humeri show no trophic changes.

Work on blood chemistry, urine and basal metabolism is under way. As the patients are scattered and chiefly in rural districts this technical work is necessarily very slow. Absence of constant findings at present warrant no report.

The muscles usually involved are:

Muscle	*Nerve*	*Cord*
Rhomboidei	Posterior scapulæ	5 Cervical
Trapezius	Spinal assessory Cervical plexus	Sp. Cord and 3 & 4 Cervical
Teres minor	Circumflex	5 & 6 Cervical
Teres major	Lower subscapular	5 & 6 Cervical
Supra scapular and Infra spinatous	Suprascapular	5 & 6 Cervical
Deltoid	Circumflex	5 & 6 Cervical

and occasionally, though to a less marked degree of intensity, the

Muscle	*Nerve*	*Cord*

Biceps	Musculo cutaneous	5 & 6 Cervical
Brachialis anticus	Musculo cutaneous Musculo spiral	5 & 6 Cervical 5 & 6 Cervical

Timme (1) believes there is a definite relationship between the pineal gland and progressive muscular atrophy. Other recent investigators (4) support the theory of a disturbance of the endocrine glands in widespread muscular disturbances.

In as much as the disease generally appears first about puberty, a time of life in which there is a decided change of endocrine secretions, an endocrine imbalance may be rightly suspected as playing an important role in this symptom complex.

SYMPTOMS

The first indications to appear in the child of one afflicted is an atrophy of the rhomboid muscles. This permits the scapulæ to become winged. The shoulder blades possess abnormal movements and the head of the humeri are in an advanced position. This occurs about puberty, rarely is it noticeable before. Occasionally the patient complains of a dull ache in the shoulders, especially at night after fatigue. As the deformity progresses, the shoulders take a more advanced position. Instead of occupying the normal position with relation to the neck, they are two or three inches in advance. If a line be drawn from the head of one humerus to the other it will be some distance in advance of the neck and chest. The shoulders become bony where they, before, have been plump. Above the clavicles there appear deep hollows and the sternoclavicular junctions, from lack of cover, appear much enlarged. The neck is set in the chest in a peculiar funnellike manner. The back of the neck, from the margin of the hair downward, presents a characteristically flat, straightline appearance.

The atrophy is fairly symmetrical. In a right handed person it is not uncommon to find the right arm shrunken to a greater degree than the left. As the disease progresses the scapulæ become so winged from rhomboid atrophy that they stand out like a pair of fins—they may be grasped in the hands as though they were detached posteriorly from the body. In an erect posture this gaves a lordosis attitude (Fig. 3), the abdomen protrudes forward and the shoulder blades backward. It becomes impossible to raise the arms to a horizontal position. This wasting process lasts from several months to three or four years, then ceases to progress. In this respect it is unlike progressive muscular atrophy. One who has reached the quiescent stage may have a lighting up of the destructive condition. This has been found to be the case in toxemias, pregnancy and undue fatigue.

The loss of strength is in proportion to the degree of atrophy. There is no pseudohypertrophy in connection with the atrophy. There are no sensory symptoms except a dull ache upon fatigue. Neither are there any twitchings complained of.

General neurological examination is negative. Work on electrical reactions has not been concluded at present.

DIAGNOSIS

Numerous forms of muscular atrophy have been described. These differ from the cases under observation either in course, chronicity, muscle groups affected, intensity of impairment and general picture presented.

This particular form may be distinguished by:

1. Hereditary history. One or other of the parents is affected. Those in the family who escape the disease do not transmit it.
2. Develops in early adolescence or under muscle exercise which would ordinarily cause compensatory hypertrophy.
3. Only muscles of shoulders and upper arm involved.
4. Ceases to progress in a few months to three or four years unless other factors—toxemia, fatigue, and pregnancy—are added.
5. There are no fibrillary twitchings or sensory disturbances.
6. Peculiar lordosis attitude, advanced heads of humeri, straight line of neck behind with finned scapulæ.
7. Does not involve face or lower extremities.
8. Does not shorten life.
9. Is not due to syphilis.
10. Reflexes unaltered except diminished in proportion to degree of atrophy in muscles affected.

DIFFERENTIAL DIAGNOSIS

Cerebral atrophy.—Loss of power usually precedes the atrophy, which is either of a hemiplegic or monoplegic type. Also history of intracranial calamity.

Progressive (central) muscular atrophy.—This type begins with the small muscles of the hand. Fibrillary twitchings are present as are reactions of degeneration. These come late in life; the wasting extends to the arms; there is occasionally a spastic condition in the legs and an increase in the reflexes.

Neuritic muscular atrophy.—The mode of onset and general characteristics are distinctive. Cause may be lead or other poisons or trauma. No family history and distribution differs. Paralysis is out of proportion to the atrophy and sensory symptoms are often present. If the legs are involved the stepping gate of peripheral neuritis is seen.

Myasthenia gravis.—This syndrome is not a family one; age from about fifteen to thirty years and usually progresses to a fatal ending. Facial muscles, particularly the upper lid, are involved, causing ptosis, and paralysis of the ocular muscles may produce diplopia, difficulty in chewing, swallowing and phonation develop. There is a rapidly developing fatigue in all the muscles involved. Occasionally the muscles of the neck are involved. This terminates fatally in from three to fifteen or twenty years.

Myotonia congenita (Thompson's disease).—Any group of muscles may be affected but those of the lower extremities are more often involved. Hereditary history is prominent; begins early; is very chronic but not fatal itself; involves muscles by a hypertonus—the muscles are stiff and unyielding but upon exercise the resistance gradually disappears. Does not recover.

This series of cases seems to come into the large and motley group of muscular dystrophies or myopathies. In a search of literature the following varieties are found but differ in some respects:

In Barsickow's group (6) the children remain healthy if the parents are unaffected; is an hereditary affliction; frequently there are winged scapulæ with protrusion of the shoulders or flattening

of the chest but it differed in that it was ushered in by almost simultaneous involvement of both an upper and lower limb or both upper and lower limbs.

In Friederick's group (7) the disease appeared early and progressed rapidly to a fatal termination. The affection began by a weakness in the lumbar muscles. He also reports four brothers whose parents were unaffected but whose two uncles died of it. These cases presented fatalities at the ages of five, six, twelve and sixteen years.

In Gower's (8) cases the disease appeared early, progressed rapidly and was fatal in adolescence. Also, members of a family escaping the disease may transmit it to their offspring.

Erb's types (9) are often combined with pseudohypertrophy. He reports involvement of the glutei and enlargement of the calves.

Other types reported by Prager (10), Bregman (11), Cestan and Lajonne (12), Wirth (13), Claude (14), Marina (15), and others differ in some respects.

PROGNOSIS

The outlook at present in a fully developed case is bad. It has been shown that this is not a disease that kills. Neither does it shorten life. There are a number of victims in advanced years who enjoy good health. The only manifestation of their affliction is deformity and limited, awkward movements, no change having taken place since the breaking down at early adolescence. The natural course of the disease is to arrest at that time unless toxemias, pregnancy or undue fatigue be added. Then after additional involvement the disease again becomes quiescent.

TREATMENT

The treatment is principally expectant and prophylactic. The field of eugenics will supply the first prophylactic measures. Those affected should, in the selection of a mate, look towards one of particularly sound physical and nervous constitution. Avoid an individual in whom "the homologous genes are not strictly identical" as Dr. Danforth says. These families should be instructed as far as is known on heredity because upon them rests the responsibility. Unfortunately many hereditary conditions are kept "in closets" until after marriage, often at the expense of matrimonial harmony in years to come.

All children should be kept under observation about puberty. As it is known that fatigue produces wasting rather than development, these individuals should be spared, as much as possible, exercise involving the arms and shoulders. An occupation which will permit rest of these muscles should be selected. This care should be exercised until a more stable state of life is reached—more stable so far as the great group of endocrine glands is concerned. It is just possible that if these patients can have the susceptible muscles rested during the period of early adolescence, a time in which there is a change in secretion of pineal, testicular, ovarian, mammary, thyroid and other glands, a location sufficiently remote from the usual time of break may be reached that will permit these people to go on without collapsing under the usual factors.

Timme (1) and others (4) have shown endocrine disturbances in the muscular dystrophies. This series of cases also would be under endocrine suspicion owing to the puberty element manifested.

"A careful study of the heredity for endocrinopathic organ inferiority may help in the use of the glandular products" (16). Cases are now being studied systematically by the vegetative method relative to neurometabolic factors. Patients have submitted to gland extract administration and the results remain to be seen.

Jelliffe and White (16) state that testicular and suprarenal lipoids at times stimulate muscle growth. Carnot has experimented with fetal muscle substances with a hope of finding possible regenerating elements (16).

G. Serra (17) restored the function of muscle in twenty of twenty-two rabbits by direct neurotization. This technic enlarges the sphere to secure beneficial results in cases already developed. A spinal nerve or part of it from a healthy muscle may be switched to the affected one. Serra took the entire external popliteal nerve and also merely half of it and switched it to the gastrocnemius muscle, restoring physiological conditions so far as electric tests, myograms and preparations of the muscle and nerve were concerned.

The attempt to investigate this disease has received but little support from the affected families. Rather an attitude to hinder has prevailed, owing to a desire to conceal the skeleton in the family closet. Technical work is scanty and photographs have been almost impossible to secure. However, it is earnestly hoped by the writer that this paper will attract an interest and lead to further study of this disease now entirely neglected.

Surgery in Nephritics

DANIEL H. BESSESEN, M.D.
Minneapolis, Minn.

Surgical operations in nephritic patients are deserving of grave consideration and cautious performance. These patients are usually in a relatively weakened condition with lessened immunity against infection and increased susceptibility to the complications of operations.

A proper diagnosis of the type, stage of chronicity and grade of severity of the nephritis is necessary to determine the type of anesthesia, the length of operation and the limit within which surgical manipulation must be confined. For this purpose perhaps the most useful is the classification of Volhard and Fahr apparently accepted by E. T. Bell (1), whose practical application of pathology to clinical medicine makes worthy of wide recognition his excellent studies on nephritis.

Under no circumstance should operation be performed unnecessarily, but in a nephritic the necessity must be dire. Unless the surgical procedure will improve the condition of the patient or save life, no operation should be undertaken. When it has been decided to interfere surgically, the kidney function is determined and attention is given to the prevention of the complications of operation. The tests of most significance to the surgeon as explained by Coons (2) are the blood urea nitrogen and the phenolsulphonephthalein excretion. This author considers the phenolsulphonephthalein test as the indication of operative initiative in most cases. With a high phenolsulphonephthalein excretion, one may safely proceed with surgery. In cases of prostatic enlargement or other infracystic obstruction, as pressure of a retroverted uterus, or pelvic growth, etc., catheterization is necessary for the correct interpretation of this kidney function test. A blood urea under twenty mgm. in one hundred c.c. of blood need cause no alarm or worry about the kidneys so far as operation is concerned. With the blood urea reading between 20 and 30, the surgeon must use care. A blood urea over 30 is of grave significance. The nonprotein nitrogen carries the same significance in its interpretation as does the urea nitrogen.

The work of Underhill and Greenhouse (3) on tartrate nephritis indicates that anemia is associated with nitrogen retention. Anemia in nephritics, then, with perhaps a few exceptions means poor kidney function, and for that reason as well as for the weakness accompanying, especial care must be exercised in these patients.

The excellent review of Chace and Myers (4) on the acidosis of nephritis demonstrates that in these cases it is due to a lack of elimination with the resulting accumulation of normally formed substances. The blood is kept fairly constantly at a slightly alkaline reaction through the influence of the bicarbonates, phosphates and proteins of the blood. An increase of the carbon dioxide in the blood induces dyspnea through stimulation of the vagus centres and this eliminates the carbon dioxide, thus maintaining the normal reaction of the blood. By means of acid phosphates, the kidneys are able to excrete an acid urine from a nearly neutral blood. This is the physiological action at fault in acidosis of nephritis. The inorganic phosphates, retained within the body, increase to several times the normal. The body proteins are able to take up large quantities of acid substances without marked change in the alkaline reaction. They also form ammonia which is of considerable importance in offsetting the acidosis. In pathological cases abnormal quantities of bicarbonates are necessary, but too much may raise the plasma carbon dioxide. In severe cases, the judicious use of sodium carbonate will cause the disappearance of dyspnea and hyperpnea.

The foregoing discussions of kidney function, hemoglobin content and acidosis of the blood give consideration to the prevention of the operative complications usually following surgery in nephritic patients. These are mainly hemorrhage, which, with hypertension, may be exceptionally serious: and in the presence of anemia and acidosis—shock. The most important of all complications is a spread of infection in the kidney or an exacerbation of the nephritis. In acute nephritis where the surgical procedure deals with the cause of the nephritis, this risk must be undertaken sometimes without choice. In chronic nephritis, however, a fatal flareup may present subsequent to manipulation of virulent infections. For this reason, a delay must be urged where active infection is anticipated. Anesthesias, as ether and chloroform, will increase the injury to the kidneys confining its disturbance mainly to the tubules, while infection confines its destructive action more to the glomeruli. Both involve other portions of the kidney substance, and when the two are combined in a patient already subject to renal damage, the effect is very serious. The use of local anesthesia with or without nitrous oxide oxygen is for this reason most advisable.

In addition to the elements of hypertension, anemia, nitrogen retention, acidosis and infection—diet constitutes a very outstanding feature in the pre- and postoperative care of a nephritic. As pointed out by Mosenthal (5), Epstein (6), Newburgh (7), Chace and Rose (8), diet may decrease or increase the extent of the kidney lesion and markedly alter the strength or metabolic balance of the patient. Rest, warmth and fluid control are further necessary adjuncts to the surgical treatment of a nephritic.

SUMMARY

It is important to diagnose the type and extent of the renal lesion. With this diagnosis at hand, due consideration must be given the presence of hypertension, anemia, nitrogen retention, acidosis and infection in determining the nature and amount of operative work permissible and to prevent as surgical complications hemorrhage, shock, infection or further kidney injury. Local anesthesia with or without nitrous oxide oxygen is the anesthetic of

choice. Diet, rest, heat and fluid control add medical balance to any surgery performed in a nephritic.

New Ways for Research Work on Tuberculosis

W. FORNET, M.D.

Sarrebruck, Germany

Although science and progress seem to be synonyms, science has made hardly any progress whatever regarding its own methods. The way a modern man of science works and studies is not essentially different from that of Aristotle or Archimedes. The modern study is a little bit more comfortable and the modern laboratory a little better furnished than that of the ancients, but their inhabitants seem to have been left untouched by the course of centuries. The only real difference has become a career like any other, open to anybody.

The amount of energy, time and money wasted in science is tremendous. There does not exist any discovery or invention that, on strength of the amount of actual knowledge upon this special subject, ought not to have been made much earlier, and none either that has not to be made twice or three times over again before it is generally accepted. Lack of cooperation and want of discipline in science makes many a generation lose its chance of profiting from a new discovery.

Especially is medical science badly off in the way of development and the health of mankind has to suffer from the consequence. Every country has a medical teaching of its own and every medical teacher preaches another gospel than his foreign colleague. Medicine, too, has become a question of patriotism even more than one of science, and a truth that is not home made is kept in the dark as long as possible.

If we think of tuberculosis we ought to be ashamed of ourselves and not boast any more of scientific progress in medicine. Countless books have been written on this disease. Many doctors have devoted themselves exclusively to its treatment and still we are not yet able to prevent people from dying of tuberculosis. All we have learned is a symptomatic treatment of the disease by gathering tuberculous persons in dispensaries and by shutting them up for some time in sanatoria. That is the real aspect of the progress in antituberculosis work, of which we are so very proud.

We should soon know better if we would only allow Nature to become our teacher. We would then realize that there exists an antituberculous immunity and we would try to imitate it. But most of us do not believe in antituberculous immunity any more since tuberculin has failed to satisfy our legitimate hope. As late as 1921 Uhlenhuth, Klemperer, Wassermann and Neufeld made the Congress of Internal Medicine in Wiesbaden and the Congress of Tuberculosis in Bad-Elster unanimously vote that there existed no proof of the reality of an antituberculous immunity.

He who does not believe in immunity against tuberculosis can never hope to find a way of immunizing man or beast against tuberculosis. He will consequently profess a dangerous nihilism that would doom mankind forever to die of tuberculosis. But happily nature is less cruel than man. Day by day it teaches us the reality of antituberculous immunity if we were only to pay heed to simple facts, instead of listening to scientific theories.

Burckhard, Naegeli and many other authors have proved that out of a hundred postmortem examinations, ninety reveal the existence of tuberculosis. As only ten per cent. of all mankind actually die of tuberculosis, eighty per cent. of them must have overcome the infection with tubercle bacilli, i. e., they must have become immune against this disease.

Loomis examined the bronchial glands of fifteen patients who had died of acute diseases, but not of tuberculosis, and found in six of them living tubercle bacilli. Pizzini obtained the same results by the careful examination of forty persons and Spengler demonstrated the presence of virulent tubercle bacilli in the glands of six children that had died of diphtheria and other conditions.

All these researches prove that the presence of tubercle bacilli in the human body does not necessarily mean tuberculosis and that we are endowed with a remarkable degree of immunity against this disease. The possibility of an antituberculous immunity alone can make us understand the marvellous effect of the high altitude cure in even advanced cases of tuberculosis. Every one of us will remember at least one case where that cure has restored fully and definitely the health of a tuberculous patient, and this one case can not but teach us that antituberculous immunity is a fact, that sooner or later we must and will learn to reproduce it at will.

Hitherto all our endeavors experimentally to im-

munize man or beast effectually against tuberculosis have remained unsuccessful. This failure is all the more astonishing as the germ of tuberculosis was discovered many years ago. It seems as if Koch's bacillus were not subjected to the microbiological laws, the observation of which has allowed us to master a great many of other infectious diseases. In tuberculosis there exists no agglutination test as in typhoid fever, no complement deflection as in syphilis, no vaccine as in rabies and no serum as in diphtheria.

Taking into consideration that there does exist an effective antituberculous immunity and that the laws of nature suffer no exception, our failure in converting the tuberculous weapon into an antituberculous armor can only be caused by some fundamental error about the biology of the tubercle bacillus. To find out that error would mean to open a new pathway to research work in tuberculosis, that seems to have come to a deadlock years ago.

As Koch's bacilli behave quite differently from all the other pathogenic germs and as we want to find an explanation for this exceptional behavior, it seems necessary to review all its well known biological properties, hoping to find out one that distinguishes it from those pathogenic germs that have already yielded to our methods of immunology. This special property might become the key to the secret the tubercle bacillus has guarded so jealously until now.

One peculiarity of the tubercle bacillus and its most striking one is its acid resistance. This property of not being easily stained by aniline dyes and of keeping that stain tighter than any other microbe is due to its waxen fatty membrane. Perhaps it is just this membrane that gave the tubercle bacillus its exceptional position in immunology. As in spite of so many endeavors the acid resistant tubercle bacillus could not be converted into an immunizing antigen, and as on the other hand immunity does exist in tuberculosis, natural antituberculous immunity is possibly not produced from this acid fast germ, but from some other form of the tuberculous virus.

Starting from this point of view we tried to find out if this fatty waxen membrane forms an integral part of the tubercle bacillus or not. We therefore tried to remove the fatty waxen substances, a procedure that several investigators had carried out before, though with quite another aim. They either wanted to know the exact amount of fatty waxen substances of the tubercle bacillus like Hammerschlag, or they wanted to study them like Goris, or they just wished to see what happened, if they defatted it, like Aronson and Uhlenhuth (2). All these experiments meant the application of wellknown chemical methods, but these routine methods of chemistry would not have done for our purpose of investigating if the tubercle bacillus could do without its fatty waxen membrane. All these methods were too radical and would in the same time have destroyed or altered the albuminous nucleus that we just wanted to keep intact.

We therefore applied a method that we had found useful in the purification of smallpox vaccine (3, 4). We had then observed that the vapors of ether and other fat dissolving liquids possess a far greater dissolving power than the liquids themselves, while they left the albumen absolutely intact. Treating an emulsion of tubercle bacilli energetically with vapors of ether, we saw that the bacilli were killed within less than ten minutes, while it takes the liquid ether many hours to sterilize such an emulsion. When we continued this process for some time, the tubercle bacilli began to lose their acid resistance and an emulsion thus treated by vapors of ether would soon settle in three distinct layers. The bottom layer contained unaltered, acid fast tubercle bacilli, the middle portion represented an emulsion of partly defatted tubercle bacilli and the top layer was formed by a thick stratum of fatty cream.

If the acid fast membrane represents no vital part of the tubercle bacillus its removal must have left unaltered its biological properties and their experimental demonstration must even have become easier without that membrane. This supposition proved to be true. The emulsion of defatted tubercle bacilli is in fact specifically agglutinated by serum of tuberculous persons, but not by that of healthy individuals. When used as antigen in Bordet's complement deflection it prevents hemolysis together with antituberculous serum. When injected into animals it causes the formation of agglutinines and other immune bodies. When administered to tuberculous animals or persons it seemed to influence the course of the tuberculous infection favorably.

We have had no opportunity of studying the important question of the prophylactic and therapeutic value of these defatted tubercle bacilli more closely, and we had to content ourselves with agglutinating tests that we carried out on a large scale. The emulsion of defatted tubercle bacilli soon became a valuable help for the detection of tuberculosis and for the control of tuberculosis under treatment. This tuberculodiagnosis was also successfully used by school doctors.

That the fatty waxen membrane represents no vital part of the tubercle bacillus could further and definitely be proved by the observation, that defatted tubercle bacilli will still play an important part in the prevention and treatment of tuberculosis, as well as vaccine as antigen for the preparation of an antituberculous serum.

The fundamental fact that the waxen fatty membrane of the tubercle bacillus may be wanting and that the naked defatted tubercle bacilli represents the two and perhaps the only useful tuberculous antigen has been fully confirmed by Wassermann (2) and quite recently by Dreyer. Wassermann removes the fatty substances by treating tubercle bacilli for several months with the fat dissolving tetraline together with liquid ether instead of its vapors. Dreyer obtained the same effect by boiling the tubercle bacilli for four or even twelve hours at 100° C. together with formalin and acetone.

It is most astonishing to see that in Dreyer's experiments the tuberculous antigen, unlike any other microbiological antigen, proved to be so resistant to heat and that the tuberculous albumen should not have been coagulated at 100° C. We must examine with great care any further publications of Professor Dreyer on this point. This noncoagulabil-

ity of the tuberculous albumen represents the really original part of Dreyer's discovery, unless his remarkable results should be due to a greater or lesser extent to the effect of a protein therapy with the defatted and boiled albumen of tubercle bacilli.

The new facts about the biology of the tubercle bacillus, described by us in 1921 and confirmed by Wassermann and Dreyer in 1923, might have become known and be put into practice many years before if there existed something like a scientific collaboration. Nonacid resistant, i. e., defatted naked tubercle bacilli, have in fact already been seen and described by a great many authors, of which we quote as the most important ones: Gottschlich and Ehrlich (1886), Metchnikoff (1888), Ferran (1897), Marmorek (1901), Much, Auclair and Paris (1907), Betegh (1908), Maher (1910), Frei and Pokschischewsky (1911), Benians (1914), Dixon, Wherry and Shermann (1913), Dostal (1916), Vaudrener (1921). If the careful observations of these and other investigators had not been systematically neglected and if the fact that so many workers had independently from each other come to the same result, had been taken into conscientious consideration, we should most probably have efficacious and generally adopted methods for the eradication of tuberculosis.

There are various reasons to believe that wherever any tuberculous antigens have practically proved to work less unsatisfactorily than the majority of all the other socalled preparations, derived from Koch's acid resistant bacillus, that all their authors have actually worked with tubercle bacilli of a diminished acid resistance. That seems especially to be true with Calmette's and Besredka's antigen for complement deflection with the homogenous culture of Arloing-Courmont, with the therapeutic preparations of Ferran, Friedmann, Dostal, Marmorek and Spahlinger.

Among these authors Ferran and Marmorek are the only ones who have realized this fact themselves and intentionally have selected primitive or alpha forms among their tubercle bacilli.

It is to be hoped that, now general attention has been drawn to the importance of defatting the tubercle bacillus before using it as antigen for diagnostic, prophylactic or therapeutic purposes, that a collaboration of all those workers specially interested in this question will establish itself at last and that the practical result of this collaboration will soon make good for all the time and labor lost by undisciplined research work. In fact, it would be worth while if the hygienic section of the society of nations or any other international institution were to take over the promising task of promoting and organizing this international collaboration of antituberculous research work.

A complete bibliography will be included in the author's reprints.

An Aid to Early Diagnosis of Pulmonary Tuberculosis

A. H. WERNER, M.D.
New York.

We all agree that the prognosis of an ultimate complete recovery in tuberculosis is the more favorable the earlier the tubercle bacillus is discovered. Many cases of an active tuberculosis have shown again and again a negative result in sputum examination. This was not due to any neglectful or cursory examination of the slides, but to the old method of staining with carbolfuchsin, the Ziehl-Neelsen method of staining tubercle bacilli.

Just lately two cases of tuberculosis came to my notice where the fallacy of the Ziehl-Neelsen method was plainly demonstrated. In each case a number of slides were prepared at four different occasions and all showed a negative result. In using the Schulte-Tigges method the very first slide proved positive for tubercle bacilli, in both instances revealing a Gaffky No. IV (two to three bacilli in each microscopical field).

For the benefit of those who are not familiar with the Schulte-Tigges method, I will give it in full:

SCHULTE-TIGGES METHOD

1. There is no need of making a thin slide; a fairly large particle of the sputum is placed upon a slide and distributed by rubbing another slide against it, making a fairly thick layer of sputum on each slide, which has the advantage that we have two slides in less time than it takes to make one.

2. Flood the slides with carbolfuchsin (ten c. c. of saturated solution of basic fuchsin in nineteen per cent alcohol, and ninety c. c. five per cent. carbolic acid).

3. Heat the slide to steaming and continue the heating for one minute. Avoid slide getting dry through excessive heating.

4. Wash off the excess stain with tap water and decolorize in sodium sulphite (ten per cent. aqueous solution of sodium sulphite). This solution should be renewed at least twice a week. Care should be taken that the slide is completely decolorized.

5. Wash thoroughly with tap water, and counterstain with picric acid. (Saturated aqueous solution of picric acid).

6. Wash with tap water and dry, and examine. The tubercle bacilli are red, the background is pinkish yellow. It will be noted that the Schulte-Tigges method is not more difficult than the Ziehl-Neelsen method, but the results reveal from thirty per cent. to fifty per cent. more positive sputum than in the latter method.

Therefore, in the interest of our patients, whenever we suspect a tuberculous pulmonary lesion and a sputum examination is made, the Schulte-Tigges method of staining should be insisted upon.

110 WEST THIRTY-NINTH STREET.

Shoeing

Z. B. ADAMS, M. D.
Boston

An inspection of feet in a large hospital clinic, not only those that come to the orthopedic department because of symptoms arising directly or indirectly from the feet, but also the feet that are seen throughout the hospital, show deformities and defects which are undoubtedly caused by the improper fitting of shoes.

This improper fitting is done not only in the small shoe stores, but in the largest and best shoe stores of the country. Many of the shoes manufactured today are excellent if properly fitted, but undoubtedly there are now manufactured many shoes labeled with orthopedic names which are dangerous, and simply freak shoes. These shoes will not be discussed or analyzed in detail in this paper, but simply the glaring defects in such shoes, as a class, will be pointed out.

RESULTS OF IMPROPER FITTING

Shoes are fitted too short and too wide. This extra width is used to get the foot crowded further forward in the shoe. The common defects that are caused by this short shoeing are crumpled toes, hammer toes, toes that are moulded one into the other so that they are creased, hallux valgus, bony outgrowths on the first metatarsal head (with or without bunion), spreading of the metatarsal shafts, toes that are flexed on the dorsum of the foot and curled, callouses on the knuckles of the little toes, callouses under the heads of the metatarsals, anterior metatarsalgia, humps on top of the foot at the junction of the first metatarsal with the internal cuneiform, pronated feet, flattened feet, and shortened tendo-Achilles. Besides these there are some other defects not mentioned, not only of the feet, but of the hips, knees and ankles, which are directly dependent upon the shoeing, and the resulting foot defects.

To be able to walk properly, the shoe must fit the foot, not bind it. There are plenty of good shoes in the shops that will fit almost every foot accurately. If there is any criticism of the stock carried in the shoe stores it is that the narrow sizes are not to be found. It is not my purpose to recommend any make or model of shoe, as stated there are many good models—but to point out that it is possible to ruin people's feet by improper fitting when the shoe used is of excellent shape and model. It is not the model in many instances,—it is the way the shoe is applied to the foot that does the harm.

During the war, in the Army, we had the Munson last, an excellent shoe, and yet, by improper fitting, much harm was done and many men were temporarily made incapable of duty by improper shoe fitting. Correct fitting relieved these men, and eventually enabled them to return to duty.

MOTION IN THE JOINTS OF THE FOOT

The metatarsal phalangeal joints and the joints between the phalanges (the junction of a condyle with a slightly cupped end) are capable of considerable upward and more downward swing. There is a slight lateral motion, and a little rotary motion at these joints. But the tarsometatarsal and midtarsal joints are made, with the exception of the scaphoid to the astragaloid head, by flat surface opposing flat surface, and these joints are not capable of any upward and downward swing, but are simply shock absorbers. The lateral swing of the foot takes place chiefly in the subastragaloid joint, around the head of the astragalus as a pivot. The motion of the foot in dorsal and plantar flexion is at the tibio-astragaloid union.

FAULTY AND FREAK SHOES

The shoes with inwardly twisted front, that is, when the front of the shoe is swung inward from the longitudinal axis of the body of the shoe, are freaks. A shoe is a housing for the foot, and the front of the foot does not swing inward as these shoes do, but extends straight forward. When a foot is put into these intwisted shoes, the small toes are cramped inward and there is an empty bag of leather on the inner side of the great toe. If this empty bag is pressed down inside the great toe, you will find the toes are crowded into a stubby, pointed space.

THE SHOE WITH A FLEXIBLE SHANK

The midtarsal and tarsometatarsal joints are not capable of any great excursion of motion. As mentioned, they are square ended, and are simply shock absorbers. Shod in a shoe without a shank, when this portion of the foot comes down under a load, it meets a surface which immediately drops away from under it, for there is nothing for the midfoot to rest on. If there is no heel, the ground furnishes this surface, as in a moccasin, tennis shoe or sneaker. But a stout steel shank is a necessary accompaniment of a boot heel, and the shank must reach from the front of the heel way forward to where the tread rests on the floor. A foot does not need to be held up, but a surface must be furnished on which it can rest. Light and active people may, perhaps, get along in shoes without shanks, but had the soldiers, carrying heavy packs, been shod in shoes without steel shanks, we should have had an army of cripples.

PLACING OF THE FOOT IN THE SHOE

The human foot has a flat, anterior portion, the toes. This portion begins at the metatarsal phalangeal junction and extends forward. It is thicker on the great toe side. The broadest point is from about the middle of the great toe straight across to the tip of the little toe. This is the normal foot, but, unfortunately, many feet have been so crowded forward into the toes of shoes that the little toe no longer stands out, but is curled against, or sometimes under, the fourth toe. The foot should be so placed in the shoe that the tip of the little toe comes at the very widest part of the sole. This will bring the

distal end of the second, third, and fourth metatarsal heads just under the region of the vamp seam, and the anterior flat portion of the foot will be in the anterior, flat portion of the shoe. The amount of empty space beyond the ends of the toes will vary with the length of the toes and the style of the shoe. Roughly speaking, there should be an inch of empty shoe beyond the ends of the toes in the blunt toed shoes, such as the Munson last; with short toes there will be more room, with long toes, less. In pointed toed shoes there will be more than an inch.

When the region of the vamp seam crosses the foot at the metatarsal-phalangeal junction the head of the first metatarsal is behind this seam and comes into the pocket made by the rising of the shank and the cutting in of the sole at the front end of the shank. This puts the most prominent point of the first metatarsal head just above and behind this rounding corner of the sole. The head of the fifth metatarsal will then occupy a less deep corresponding pocket on the outer side of the shoes.

The counter of the heel and waist of the shoe should fit closely against the sides of the heel and foot, not to squeeze it, and be of such width that there is a space between the lacing, for the lacings should hold the foot back in place against the counter. The foot should never be held back by pressure on top of the foot over the metatarsal shafts or heads, by the vamp seam. In fact, when fitting a shoe, before lacing, it should be seen that there is a space above the foot at the vamp seam when the whole body weight is put on the foot.

When people enter a shoe store and a clerk approaches with a measuring stick and measures their feet, they must remember that they are dealing with a clerk, a salesman,—but only in rare instances with a man who really knows the first rudiments of fitting. People must learn for themselves how to shoe their own feet,—where the foot should be placed in the shoe. A shoe that fits is as comfortable when new as it is the day it is thrown away. The process of breaking in new shoes is really moulding the feet as well as the shoes.

Adenosarcoma of the Right Tonsil Cured by Radium Emanation Seeds*

I. GLASSMAN, M.D.
New York

CASE.—E. N., female, eighty-one years of age, in fair health. Examination of the throat revealed a large mass the size of an orange protruding into the pharynx and extending downward toward the neck to the under surface of the right lower jaw. The mass was easily palpable, externally. The patient gave a history of having noticed the growth of the tonsil three months previous to the beginning of the treatment. She complained of difficulty in breathing. At night she experienced a sensation of choking and her sleep was considerably disturbed. There was also a marked mechanical interference in swallowing. On physical examination another mass, the size of a large grapefruit, was found in the left groin. This mass was probably malignant in nature, since it was infiltrating and adherent to the surrounding tissues.

On April 25, 1923, the tumor mass of the throat was injected with two per cent. novocaine solution and thoroughly anesthetized, then emanation "seeds," consisting of small glass capillaries containing radioactive substance, were imbedded in the mass. Four seeds of one millicurie each were inserted through an instrument into the centre of the new growth and three seeds containing one half a millicurie each were then inserted around the mass. There was no bleeding or any other discomfort to the patient. (Figs. I and II.)

The small glass tubes are placed inside of a hollow needle through which a plunger is thrust. The tube as well as the needle and plunger are sterilized by boiling. After inserting the needles into the tumor they are withdrawn a few millimetres to leave a small channel, thus avoiding the danger of breaking the tube.

On April 28th, three days after the implantation, an observation was made and the tumor found considerably reduced in size, so that the uvula, while resting on the tumor mass originally and considerably deviated to the left of the median line, was free. The tumor at this time was easily reduced to one half of its original size.

Another observation was made on May 7th. At this time the anterior and posterior pillars of the tonsils were plainly visible and the throat was free from the tumor mass, also the mass was not palpable externally. At this time the patient complained of slight malaise and pain on that side of the throat. There was slight superficial sloughing and the patient was directed to use an antiseptic mouth wash. (Fig. 3.)

The last observation on May 14th showed no tumor mass and the patient was entirely free from symptoms. Her swallowing was not interfered with; her breathing was easier, and her general condition was good.

The advantage of using emanation seeds in preference to radium itself may be tabulated as follows:

1. Radium is not accessible to all practitioners and it requires special technic with a thorough knowledge of the quality and action of the rays before one can be qualified to apply it; while the seeds when charged with the radioactive substance and carefully calculated are easily applied, when the tumor is accessible.

2. The emanation may be put into any con-

FIG. 3.—Photograph of the mouth. Complete disappearance of the tumor mass. Anterior view. May 7, 1923.

tainer, shape, size and strength calculated according to needs.

3. The volume of emanation is extremely minute as compared with the volume of radium that will be required to produce the same intensity of radiation.

4. The small tubes of emanation may be left in the tumors indefinitely. Although the tubes may contain high concentration originally, the strength is greatly reduced by disintegration.

I wish to express my thanks to Dr. C. N. Gelber and Dr. Joseph Muir for their cooperation in making the report of this case possible.

182 LEXINGTON AVENUE.

Galvanic and Faradic Electricity and Derived Currents in General Practice*

FRANK THOMAS WOODBURY, M.D.
New York

(*Concluded from page* 6)

The question naturally arises at this juncture as to how we are to obtain the electrolytic action characteristic of one pole to the exclusion of the effect from the other pole, since the current flows equally everywhere throughout the circuit. We take advantage of a physical law, true everywhere as in electricity, that a certain applied energy, if concentrated upon a small area with terrific effect, may be made harmless by dissipating over a large area.

Our treatment electrode is called the active electrode and is just of sufficient area to apply the density of current desired, and this is attached to the pole whose effect we desire to obtain. The other electrode, which is called the dispersing or indifferent or inactive electrode, is much larger and is usually applied on the abdomen or back where there is a large surface. If our active electrode have one square inch of surface in contact with the body and the inactive electrode have one hundred square inches, then if our current be of five ma. strength, there will be a concentration of the five ma. on the one square inch at the active electrode, but each square inch under the dispersing electrode will have only five one hundredths ma. or one twentieth ma., which is negligible in its effect.

When desiring only the polarity effect of our active electrode, we use platinum, gold or carbon electrodes, which are ineffectively electrolyzed with either pole; copper, zinc or silver, as our active electrode, when employing the negative pole. In either event, if used bare, they will cause the characteristic caustic effect of the pole. They must be covered with a bibulous substance to prevent this effect. If we use on the covering a solution of our medicament, say a metallic salt and then use an electrode of the same metal for the active electrode and apply it as the positive pole, we will enhance the iontrophoretic effect.

When a current of appreciable quantity is suddenly sent through a wire circuit there arises around the wire a cylindrical field of force, called the electromagnetic field, with a definite polarity, which may be proved by a magnetic needle brought within its influence or by the classical experiment of the iron filings. When the current ceases to pass, this mag-

*Read before the Medical Society of Bay Ridge, N. Y.

netic field of force collapses into the wire. Should another wire, even if insulated, be placed at right angles to this field of force an electrical impulse or flow of electrons would take place in the wire in one direction when the field of force arose, and in the opposite direction when the field of force collapsed. This is called induction.

Again, the sudden make and break of the current will just as suddenly start and stop the electrons in the first wire.

If the body be a part of the electric circuit, when the current is abruptly made and broken we have a sudden impulse and arrest of motion of the hydrogen ions combined with the rise and collapse of a field of magnetic force in the tissues, which incite heat and pain with consequent muscular contraction and the degree of both would depend upon the polarity of the exciting electrode, the milliamperage used and the abruptness in arriving at the full strength of the current, together with the rhythm periods of the interruptions. While the current flows there is no interpolar effect of irritation and no neuromuscular response, only heat and increased blood flow. There are, however, polar effects.

From these facts we derive the following suggestive ideas:

First, when giving galvanism we must always go from zero to the intended milliamperage slowly and likewise when finishing the treatment the current is reduced to zero gradually.

Second, we can make use of this reaction in the diagnosis of abnormal nerve muscle conditions; and

Third, we may use this interruption in a rhythmically repeated manner for treatment purposes.

The character of the physiological response is governed entirely by the frequency of the interruptions and the relation between the period when the current is flowing and when the current is not flowing.

The most interesting interrupted current is called after its proposer, the Leduc current. It is obtained by interrupting a direct current of only one or two milliamperes up to about one hundred times per second. By this current Leduc claims that he can produce experimentally in animals single muscular contractions, tetany, local anesthesia, general anesthesia, which he calls electric sleep (7), coma, paralysis of the heart and respiration, and finally death.

The anesthetic action can be explained, says Turrell (8), "by the exhaustion of the sensory receptors by overstimulation, a phenomenon similar to that of the fatigue resulting in the recovering end plate of motor nerves from electrical overstimulation, the overstimulation in each case being occasioned by the frequently recurring hydrogen ion concentration." We must remember that the current has polarity, therefore to prevent polarity effects we must use equally sized large area electrodes.

The infrequently interrupted galvanic is nutritional and developmental in its action because there is a longer time for the flowing current to have its effect. The socalled interrupted galvanic of many machines is one in which there is a momentary flow with a long period of intermission. A variation on this modality is the interrupted galvanic surge, in which the milliamperage rises and falls between maximum and zero at a regular rhythm with a regular period of rest between. Such a current in effect is the one of Lapicque, which is used to exercise a paralyzed muscle without exciting contractions in neighboring antagonistic healthy muscles. The necessary strength is obtained with the most cautious gradual increase of current.

We now come to a consideration of alternating currents. These are really rhythmic surges of alternating reversal of polarity. The result is that we have only the interpolar nutritional and exercising effects, without polar chemical effects, as each succeeding surge neutralizes the polarity effect of its predecessor. When expressed graphically the flow of current represents a sine wave, hence the name of galvanic sinusoidal.

The current is purely mechanical and intended for exercise only with its resultant nutritional and developmental effects. It must not be attached to a paralyzed muscle for extensive application and it must run in slow cycles, a few per minute, corresponding in rhythm to the time of ordinary contraction and relaxation of the parts; of the abdominal muscles for example in rhythm with respiration. When used for relaxing fibrosis or for expressing exudates from contractible tissues the rate may be increased.

As we increase the frequency rate of alternations, we of course increase muscular response, until we get to a point where the muscle cannot relax before the next contracting impulse arrives and hence we have tetany. If the alternations increase to beyond ten thousand alternations a second, no muscular response is perceptible.

We note with the use of the galvanic sinusoidal current a painless contraction of physiological character as obtained by the rhythm of the reversal, which causes increased nutrition of the muscle and when applied to large groups of muscles tends to relieve the heart, slow the pulse, increase metabolism, reduce adiposity and raise blood pressure all without fatigue. On the contrary after a patient undergoes this treatment upon the Bergonié chair for the reduction of obesity there is a feeling of vigor and refreshment. This is also a good treatment for any tired muscles, as in Charley horse or lumbago, or during convalescence.

There are two apparatuses on the market with special names which give alternate rhythmic surges having the effect of the galvanic sinusoidal. They are the Clonophore and the Morse. Their action is purely mechanical.

The next type of alternating current is an induced current coming from the secondary coil of an induction apparatus called a faradic. Its characteristics are a high voltage, a very low milliamperage, and a very rapid alternation with a faint polarity. The voltage can be increased at the expense of the milliamperage by pushing the secondary over the primary coil. The more lines of force from the primary cut the coils of the secondary, the higher will be the voltage, the lower the milliamperage and the more painful and stimulating will be the muscle response.

Gaiffe of Paris makes a machine in which the secondary swings backward and forward over the primary thus giving a surging effect. A combined galvanic and faradic current, called the DeWatte-

ville, was invented to give more volume and add polarity.

None of these derived currents, save the galvanic sinusoidal, have held the field in the face of the static and high frequency modalities. In considering the indications for these various currents we are guided by the physiological response to a large degree and also by the clinical evidence.

I have thought it well therefore to present some clinical evidence herewith.

CLINICAL DATA

Sinclair Tousey and W. M. Clark have in different places testified to the sclerolytic effect of the negative pole at three to fifteen ma., especially when it is of adequate size, in the softening of scar tissue, especially superficial fibrosis from burns, scleroderma, Dupuytren's contracture and false ankyloses. While they suggest that chlorine iontophoresis may be decidedly helpful, it is not operative in deeper parts.

For superfluous hair the negative pole is used, but it is a treatment which may well be left to the beauty parlors, as it is tedious, taking sometimes a year to accomplish complete results. Again small hairs are stimulated to grow and require removal.

For alopecia Shoemaker (9) advises the Scotch douche with shampooing and three or four milliamperes of negative galvanism either through the moist hair or by a metallic bristled brush. The current is increased to tolerance. The faradic is used similarly with the brush until the scalp is quite erythematous.

With sebaceous cysts a bipolar electrode applying an electrolytic current of great density or a monopolar needle electrode as negative pole can both be used, the effect being a softening of the contents and destruction of the lining membrane. Birth marks, port wine stains and other forms of nevi are treated with electrolysis and bipolar electrodes, small areas at a time, allowing the reaction to subside. For acne and acne rosacea zinc or copper iontophoresis, five to twenty, is used for each comedone. Boils and carbuncles yield readily to the same treatment.

Erysipelas, according to Clark (*ibid*), is amenable to magnesium iontophoresis, five to fifteen ma., used daily. Chronic ulcers of the legs and beginning small epitheliomas yield to zinc iontophoresis. Leduc uses two ma. to the square centimetre of surface and an application of fifteen to twenty minutes. Cocaine, also by iontophoresis, may be necessary. The surface of the ulcers is covered a dead white by zinc deposit. A little later the surface turns red and is somewhat inflamed for about a week. Soothing applications are required. Several applications are usually necessary.

The nerve conditions which most commonly call for the use of constant current are neuralgia, neuritis, paralysis and muscular spasm. These are usually associated in groups, plexuses or ganglia. In injuries and diseases of the nerves the constant current is of great importance in making diagnosis and prognosis. The reaction known as the reaction of degeneration and which appears in Wallerian degeneration is one which we have not space to give, but it also allows of a prognosis as to length of convalescence and degree of recovery.

An early diagnosis permits relief of a beginning neuritis before paralysis and fibrosis occur and wasting enters the picture. This is most important and is a point on which the medical profession in general is in error, since almost invariably the surgeon or internist believes that early use of electricity in any form is harmful, while later it may be allowable. I leave it to your judgment whether an exudate is not more readily removed while still fluid and plastic than after it is organized and fibrotic.

In brachial neuritis a large dispersing electrode is placed on the cervical vertebræ with a smaller anode in the supraclavicular space, especially including any tender spots. Five or six ma. are passed for five minutes. A roller electrode may be used. These treatments will have their greatest effect and greatest value during the acute stages. If given early the pain, inflammation and tenderness will often disappear in a remarkably short time and no paralysis or atrophy need be expected.

With the sciatic nerve and its distribution a longer time and stronger currents will be needed. A large cathode is placed on the sacrum or lumbar vertebræ and a foot tub containing hot salt water is used for the anode. The treatment is ten to fifteen ma. for ten minutes, or stronger, if agreeable. Roller electrodes may be used for the active pole along the sciatic, especially on the tender spots.

The same general plan is pursued in trigeminal or multiple neuritis, intercostal neuralgia and herpes zoster. In the vomiting of pregnancy the positive pole is applied over the clavicle and the negative over the pit of the stomach. It is almost invariably successful, according to Neiswanger.

Leduc and others report a certain number of cures of tic douloureux. A two per cent. solution of sodium salicylate is applied by the negative pole to the part of the face affected and a current of twenty ma. is given for an hour. The effect here, however, must be ascribed, not to the iontophoresis, since the pathology is too deep seated to be affected by the drug so administered, but to the interpolar heat and hyperemia.

W. J. Turrell, of Oxford, England, reports the use of the Leduc current with complete success in relieving causalgia in veterans—after all other methods tried had failed, notwithstanding the fact that in the British Research Committee's report on the diagnosis and treatment of peripheral nerve injuries, referring to the treatment of causalgia, the following passage occurs: "Little benefit can be hoped from electricity."

In the treatment of paralyses great care must be exercised in grading the dose to the weak muscles. An overdose is as bad as a whip to an exhausted animal. If we have merely an atony from disuse, then we may be a little bolder in our use of the sinusoidal galvanism. It is injudicious to employ galvanism in hemiplegia until after a period has elapsed to permit the clot or embolus or what not to attain a degree of restitution, though it may be used over the muscles to prevent atony. In the toxic and postinfectional palsies, as well as poliomyelitis, galvanism to the nerve area and sinusoidal galvanic to the muscles make a good team.

In all cases of spasms and contractures the sedative anode is indicated. It is not invariably successful.

In genitourinary conditions these currents are

sometimes employed. Paralysis of the bladder, incontinence of urine, functional impotence, spermatorrhoea and frequent nocturnal losses, renal colic, simple hypertrophy of the prostate are all benefited by faradism. In orchitis galvanism followed by faradism affords some relief in pain by absorption of the swelling.

In urethral and ureteral stricture negative electrolysis is specific, and in gonorrhoea zinc iontophoresis is very efficacious. Negative electrolysis of hydroceles is done by puncture, using twenty to fifty ma.

In gynecology these modalities have their most happy effects and it is surprising that the gynecologists have continued to practise surgery for conditions which are remediable by electrical means. The evidence is good, sufficient and can be repeated by any one who informs himself upon the subject. A careful perusal of Sloan's work on gynecology or Dr. Massey's books and numerous writings will find ample justification for this statement.

The following conditions are curable by copper or zinc iontophoresis: vulvitis, vaginitis, endocervicitis, endometritis, salpingitis and gonorrhea.

The positive pole positively controls hemorrhage and in the case of fibroids is doubly efficacious without sterilizing the woman.

The treatment of fibroids is at present a contention between surgeons and radiologists. Radium and x ray having possibly the best of it, but Apostoli developed a galvanic technic by which he obtained a permanent benefit in ninety-five per cent. of these cases, results which were repeated with even better success by Keith of London and Massey of Philadelphia.

The technic is simple but must be adhered to. Using a nonionizable positive electrode in the uterine cavity, a current of thirty to forty ma. is very gradually turned on, remains at this point for a few minutes, then is increased cautiously. Usually fifty ma. will be sufficient for the first treatment. On the first sign of pain the current should be reduced. The maximum is maintained for about ten minutes. Later heavier currents may be employed, but with a reduction in time. The patient must expect colic and increased discharge for the next twenty-four hours, and rest in bed is highly advisable. The treatments are given three times a week, or less if necessary. Sometimes fibroids are treated through punctures through the vaginal vault.

Massey gives the following contraindications for this procedure: Menstruation, pregnancy, an abscess in any pelvic organ, acute metritis or perimetritis. Dysmenorrhea due to infantile uterus is much benefited by negative intrauterine galvanism and the galvanic sinusoidal. In other cases due to inflammatory exudates Apostoli's method is indicated; in subinvolution with a boggy uterus the positive galvanic treatment is specific. In amenorrhea negative galvanism is indicated, using five to fifteen ma., followed by faradism; of course, any anemic cause must be corrected. The faradic current is recommended in threatened abortion and in placenta previa, but only with mild currents (premature delivery may be brought on by strong currents), also in subinvolution and prolapse.

This is but a sketch of electrotherapy in gynecology, and to those interested I can with heartiness recommend the books of G. Betton Massey of Philadelphia and Samuel Sloan of Glasgow.

We shall now hastily review some other conditions. Of late we have been hearing about the viscerosensory reflexes, and quite a little has been gained from knowledge of Head's zones and Abram's spondylotherapy and the work of Arnold Snow. Certain reflexes are now established whereby internal organs may be affected by stimulation of certain skin areas or intervertebral spaces upon the posterior nerve roots directly, not alone by pressure or vibration, but also by incandescent radiation and, what interests us here, faradism and galvanic sinusoidal applications. Gastralgia, cholecystitis, splanchnic neurasthenia, and even visceroptosis; blood pressure and heart rhythm are influencible by these applications to appropriate intervertebral spaces.

In myalgia or myositis, torticollis and other spasmodic conditions the faradic current often has a soothing effect. In headaches, such as migraine or from neurasthenia or gout, or in cases of insomnia mild galvanism will frequently give relief, if applied from nape of neck to forehead. The bitemporal application causes dizziness and syncope.

In diseases of the ear attended with acute infections zinc iotophoresis is very valuable, while in sclerolytic conditions chlorine ions or simply negative galvanism are suitable. Polypi are amenable to electrolysis.

In catarrhal conditions of the nose and throat with swollen mucous membrane the positive pole shrinks and relieves and the use of zinc iodide by either pole is antiseptic.

In infectious diseases of the conjunctiva the copper ions are indicated and cocaine, eserine and homatropine can be introduced by iontophoresis. Pterygium is removable by electrolysis, using a fine platinum needle. Faradism has been used in choroiditis and interstitial keratitis according to de Schweinitz.

I regret that space has compelled only a review of the subject, and I wish also to emphasize the fact that while by these treatments the results mentioned are obtained, other physical means, as high frequency and static electricity, ultraviolet and caloradiance, x ray and radium are equally and often more efficacious, nevertheless the inexpensive portable galvanofaradic battery in the doctor's car will give wonderful service where other agents are lacking.

Practical Therapeutics

AUTOSERUM TREATMENT OF CHOREA*

JACOB DINER, M.D.
New York

In 1917 I made a report of three cases of chorea (minor or Huntington's chorea) treated with autoserum and described the technic of the treatment in detail.

At that time I discussed (1) also the rationale of the treatment as follows: "I have no definite data to advance, but would suggest the following theory: The exchange of substances from the subarachnoid spaces to the blood can be brought about with much greater ease than in the opposite direction, particularly with an increased intraspinal pressure. Assuming chorea to be an infection localized in the cord, we can imagine the possibility of the antigen finding its way into the circulation and thus stimulate the production of antibodies, which cannot find their way back into the spinal fluid and cord by reason of the lower pressure in the circulation and the obstacle offered by the choroid plexus. By introducing the serum of the patient, presumably rich in antibodies, direct into the spinal space we have, analogous to the rationale advanced by Flexner in relation to epidemic cerebrospinal meningitis, the means at hand to combat this infection, which from its mode of onset and general progress appears to be of the subacute or chronic variety."

Looking over the more recent literature I find that Morse and Floyd (2), after a careful review of the literature and subsequent original research of their own come to the conclusion that "their results suggest that a microorganism or a group of microorganisms may be the cause of chorea . . . and tend to confirm the belief that there is an intimate relation between chorea, rheumatism and endocarditis. . . ." They isolated a streptococcus from a case of chorea and state. . . . That the fact that it (the streptococcus obtained from the blood culture) caused lesions in the brain and meninges of rabbits similar to those found in the brain and meninges in fatal cases of chorea suggests that it was also the cause of chorea in the child."

Graves and Paige (3) hold "that it is possible that acute chorea is due to the action of bacterial toxins, perhaps a selective action, upon central nerve cells in persons whose inherited nervous instability makes them more readily subject to such toxic action." Thus answering Osler (4) who offers "the prominent physical element as one of the most serious objections to the conclusions of Morse and Floyd, since there can be no doubt that ordinary chorea may rapidly follow a fright or a sudden emotion," Alfara (5) believes that chorea is the result of the action of bacterial poisons on the basal ganglions, particularly the striate body. Schroeder (6) quotes various authors and investigators in support of the pathology in chorea and meets Cobb's (7) objection to the organic theory on account of attacks following fright and sudden emotion by pointing out that emotional shock may activate an organic lesion which has previously failed to show overt symptoms and summarizes as follows: "Aschoff nodules have been demonstrated in the heart muscle of a twenty months' old child who had chorea and a fulminating rheumatic carditic and pericarditis. Advances in the study of the physiology of the basal ganglions make it seem likely that the chief pathological changes in chorea minor occur there."

In view of these contributions to our knowledge of the pathology of chorea I feel that my theory of the rationale of autoserum treatment is fairly well supported. During the past eight years I have seen and treated fifty-nine cases of chorea minor by the intraspinal serum method. These patients were treated in Fordham and Knickerbocker hospitals in New York city, in private sanatoria, and in the patients' homes and are classified as follows:

Age: youngest, four years; oldest, nineteen; average, eleven and three tenths years. Duration of illness, from day of admission to day of discharge as cured, or improved: shortest period, four days; longest, ninety-six days; average, thirty-two and four tenths days. Previous attacks of chorea: one attack, twenty; two attacks, nine; three attacks or more, two. Total number of cases having previous attacks of chorea, thirty-one. Previous diseases (one or more) of those enumerated below: Tonsillitis, thirty-five; measles, twenty-eight; rheumatism, eight; scarlatina, six; diphtheria, six; mumps, two.

Among the cases treated the following is of special interest:

CASE.—M. K., a boy sixteen years of age, was admitted to Fordham Hospital July 1, 1921. His tonsils and adenoids had been removed a year ago. His older brother, a teacher having charge of backward children, told us that the boy was classified as eight years of age, mentally. He had had several attacks of chorea during the previous two years, was under treatment for it in various institutions, but had not obtained definite relief. An x ray of the head showed that the sella turcica was shallow and the anterior clinoid process atrophic.

After a rest of several days in the hospital intraspinous serum medication was administered and within six days the choreiform movements ceased. In less than two weeks he was allowed to walk around in the ward and later he assisted the nurses in distributing food to the other patients. About two days before his discharge from the hospital on August 22, 1921, he was put on anterior lobe of pituitary gland, one fifth grain, three times a day, and his family physician, Dr. Dreiblatt, who had referred the case to me, was advised to continue this medication for some time.

The young man called on me some time in January, 1924. He had had no recurrence of the chorea, had improved physically and mentally beyond recognition, and was working in an office in a clerical position, giving entire satisfaction.

Among the cases treated there were a number in which the patient's previous history was either not obtainable or very indefinite, since the majority of

*Read at the meeting of the American Therapeutic Society, held in Toronto, Canada, May, 1924.

cases were among children of foreigners whose knowledge of the English language was limited.

We have not been able to check up on all the cases treated, as we were unable to locate the patients. However, in the fifty-nine cases treated only one patient returned to the hospital two and half years after treatment showing choreiform movements, which subsided after a week in the hospital under dietetic care and rest.

CONCLUSIONS

1. Pathological research has fairly well shown that chorea can be considered as of bacterial origin.

2. While a focal source of infection cannot always be demonstrated or elicited from the history a great many patients do give a history of previous infection.

3. The antiserum treatment has been successful in practically all cases and deserves further investigation.

Etiology and Treatment of Rheumatoid Arthritis and Allied Diseases.—S. G. Billington and Sandison Crabbe (*British Medical Journal,* June 21, 1924) classify the socalled rheumatic conditions according to the usual causes of inflammation: physical (mechanical or traumatic), chemical (metabolic, gouty, diabetic, alcohol, etc.), thermal (heat or cold), specific (syphilitic, neuropathic, hemophilic, and the specific bacterial, such as typhoid, gonococcal, etc.) and nonspecific bacterial. Only the nonspecific bacterial group are considered, though the others must be mentioned from the point of view of differential diagnosis.

Articular rheumatism can be divided into two great groups: 1, rheumatic arthritis, and 2, the rheumatoid group, including the various types of rhaumatoid arthritis and osteoarthritis. Three stages of rheumatoid arthritis can be recognized: 1, early, with slight or recently developed joint lesions; 2, active arthritis with definite arthritis changes; 3, old standing arthritis, with or without the presence of the active disease, but with postarthritis deformities, contractures, muscular atony and wasting.

The treatment includes the following procedures: 1, Removal of the infective focus; 2, neutralization of bacterial toxemia in blood stream and affected tissue; 3, orthopedic treatment of the results of the disease; 4, psychological treatment; 5, general treatment by tonics, endocrine preparations, etc. In the first stage removal of the infective focus is usually all that is necessary. In the second stage the toxemia must be neutralized. The third stage includes: 1, the removal of the infective focus if present; 2, the treatment of the active arthritis if present; 3, the treatment of postarthritis sequelæ by electricity, massage, manipulation, exercises, or operation; 4, the use of a vaccine as a prophylactic against lighting up the disease by the orthopedic procedures; 5, general and psychological attention to the patient.

The diagnosis must be made from diseases of metabolic or chemical origin, such as gout, diabetes, and alcoholism; from mechanical conditions resulting from trauma, occupation, pressure of new growth, etc.; and from displacements, such as flat foot and coxa vara. Syphilitic, neuropathic, and the specific bacterial affections require separate consideration. The diagnosis between active arthritis and postarthritis sequelæ is most important. The three most important evidences of active arthritis are: pain apart from movement, the night pain being the most characteristic; local tenderness; and general debility with often a toxemic facial aspect.

In the first stage all foci of infection should be sought, especially in the teeth, the gallbladder and in the genitourinary system, and also in the intestinal tract (appendix). In the second stage, such drugs as guaiacol carbonate, iodides, collosol manganese, and alternating collosol iodine and collosol sulphur may be used. Peptone or other foreign proteins are of advantage. The most reliable antibacterial agent is an autogenous vaccine. The physiotherapeutic measures include the high candlepower lamp, diathermy, the static brush effleuve, the static wave, the tungsten arc lamp and the galvanic current. The operative measures include wrenching under anesthesia, open operation for removal of osteophytic outgrowths and hypertrophied synovial membrane and excision of the joint. In the psychological aspect, endocrine therapy is useful, using pluriglandular preparations.

Causes and Treatment of Otitis Media.—David T. Smith (*American Journal of Diseases of Children,* July, 1924) states that the mechanical problem in the treatment of otitis media is of vital importance. The pus must be cleaned from the external ear, and the antiseptic introduced into the middle ear where it can act directly on the organisms causing the disease. Ordinary commercial hydrogen peroxide diluted one half with water was found to be the most efficient irrigating fluid. The incision in the tympanic membrane should be long and clean, preferably in the posterior inferior quadrant. After the irrigation is completed, judged by the cessation of the frothing of the peroxide, the excess of fluid in the external auditory canal is swabbed away with cotton. A few drops of the prescribed antiseptic are dropped from a medicine dropper into the external canal. Not a single case of mastoiditis followed the use of hydrogen peroxide.

Practically all the gram negative bacteria found in cases of otitis media, except pyocyaneus bacilli, are killed by a 0.5 per cent. solution of sodium hydroxymercuribenzophenone sulphonate. Pyocyaneus bacilli are readily eliminated by treatment with two per cent. acetic acid, or preferably with 0.5 per cent. of the sodium solution which contains two per cent. acetic acid. All the gram positive bacteria found in otitis media are readily killed by gentian violet except streptococci. Neutral acriflavine has been proved more potent in the treatment of otitis media associated with streptococci, but even this drug is not entirely satisfactory.

Multiple Gastric Ulcers*

E. STARR JUDD, M.D.
AND OSCAR S. PROCTOR, M.D.
Rochester, Minnesota

In considering this report on patients treated for multiple gastric ulcers, it is necessary to keep in mind that the series covers a period of ten years, and that many of the cases incorrectly diagnosed several years ago would be correctly diagnosed now. It is only within the last few years that x ray examinations have reached their present degree of perfection in this type of cases, and it is fair to assume that an expert röntgenologist can now detect the presence of multiple lesions in the stomach and duodenum in a considerable proportion of cases. Years ago, it was believed that in most cases of dyspepsia there was a lesion or disturbance of some kind in the stomach itself, but now, by careful statistical study, it can be shown that dyspepsia is much more often the result of chronic inflammation in the gallbladder than of any other condition.

Along with the progress that has been made in laboratory and clinical methods and interpretations has come the development in our judgment as to the type of operation that is best suited for multiple ulcers of the stomach. We do not believe that radical operations are indicated in all cases, especially if the ulceration is confined to the duodenum. In the particular group being considered here, undoubtedly better ultimate results will be obtained by resection and removal of the ulcer bearing part, and fewer secondary operations would have to be performed. In order to improve the immediate results in gastric surgery, it will be necessary to find some plan by which the pulmonary complications and thromboses can be avoided.

From 1914 to 1924, 1,475 cases of gastric ulcer were operated on in the Mayo Clinic, in 247 of which there was an associated duodenal ulcer. Of the total, there were eighty-seven cases with two or more ulcerations in the stomach, and in twelve of these, a duodenal ulcer was coexistent. Thus in this series there were multiple ulcers in six per cent. Usually the number was two, sometimes three; in only seventeen per cent. were there more than three ulcerations.

*Submitted for publication November 20, 1924.

Clinically one is rarely able to diagnose multiple gastric ulcers. One case of this series was so diagnosed from the history, which was unusual, and two other cases, from the x ray findings. Three cases were diagnosed carcinoma of the stomach, chiefly because of the x ray findings; and one case because of the history and findings of an obstruction at the pylorus. A diagnosis was made of duodenal ulcer in ten cases, largely on the basis of the x ray findings. Of the twelve cases in which a duodenal ulcer and multiple gastric ulcers were present, the diagnosis was made in six, entirely because of the x ray report.

The average age of the patients in this series was forty-five years, the youngest patient being twenty-one, and the oldest seventy; seventy per cent. were males.

There does not seem to be anything distinctive in the history or physical examination to lead one to suspect multiple ulcers. The duration of symptoms ranged from five weeks to thirty-two years, the average being nine and two tenths years. One fact may be significant, that in forty-four and eight tenths per cent. of the cases the symptoms at the time of examination were continuous, and had been so for a period of from several weeks to several years, although at the beginning of the trouble, there was ordinarily the periodicity usually found in cases of peptic ulcers. The severity of the symptoms was apparently only average.

Bleeding, as hematemesis or melena, was present in twenty-seven cases (thirty-one per cent.), ranging from coffee ground vomitus to repeated profuse hemorrhages. One patient had had twenty-six more or less severe hemorrhages. Chronic perforation, of greater or less extent, was present in twenty-eight cases (thirty-two per cent). Some of the patients were in poor condition, usually due to pyloric stenosis, and in a few instances to secondary anemia. Six of the cases were syphilitic in origin.

X RAY FINDINGS

In only two cases did the x ray examination reveal definitely two ulcers in the stomach. In two

other cases there was a possibility of a second ulcer being present. Two cases were listed as negative. Five cases were diagnosed duodenal ulcer, but in these the ulcers were at or near the pylorus. Four cases were diagnosed carcinoma of the stomach; two of these were syphilitic. Ten cases were listed as lesions at the pylorus; two as indeterminate; two as prepyloric, and one as a lesion of the stomach. In the remainder of the cases a diagnosis was made of gastric ulcer. Of the twelve cases in which there were both duodenal and gastric ulcers, the diagnosis of gastric and duodenal ulcer was made in six; in five a gastric ulcer alone was noted, and in one, only the duodenal ulcer. It is clear, therefore, that although the x ray findings were positive in more than ninety-five per cent. of the cases, in only four and five tenths per cent. was there evidence tending to show the existence of more than one ulcer in the stomach. In one half the cases of duodenal and gastric ulcers, the existence of the two conditions was noted.

PATHOLOGY

Two ulcers were found in sixty-three per cent. of the cases; three ulcers in twenty per cent. and more than three in seventeen per cent. There was an associated duodenal ulcer in thirteen and seven tenths of the total number. The largest number of ulcerations was twenty-two (Fig. 1).

Fig. 1.—Resected stomach with twenty-two simple ulcerations.

If there were more than three ulcerations, usually only one or two ulcers had a deep crater with rounded, thickened edges, and much induration. The others, though varying considerably in size, usually were smaller, round, punched out, shallow, and apparently more recent. As to the mechanism of their occurrence, and the length of time they had been present, one may only guess. It does not seem too unreasonable to assume that they are infectious in origin, and possibly due to an extension of the infection from the older ulcer or ulcers.

The largest of the ulcers was five cm. in diameter, and the smallest two m.m. The majority were located on the lesser curvature near the pylorus, not infrequently in the pylorus. Others were found in practically any part of the stomach, often on the anterior or posterior walls, and less often on the greater curvature or near the cardia. Adhesions were common, particularly in the thirty-two per cent. of cases in which there was slight perforation.

In one case there was a carcinomatous ulcer four cm. in diameter, and two smaller simple ulcers. In another case there was a small carcinoma eight mm. in diameter, and three simple ulcers. In three cases the gross or microscopic findings suggested malignancy, but a definite diagnosis could not be made. The remainder of the cases, with the exception of those which were syphilitic, were simple gastric ulcers.

CASES OF SYPHILITIC ORIGIN

Five of the cases were undoubtedly syphilitic, and one was questionable only because of the negative Wassermann reaction and general examination, the local findings being typical. In three of the six cases the clinical diagnosis was either certainly or possibly syphilis; in the other three it was not suspected until operation.

The average age of the patients was thirty-five years. The x ray findings were carcinoma of the stomach in two cases; a prepyloric lesion in two; gastric ulcer in one case, and a syphilitic contracture in one.

At operation the picture was often suggestive of syphilis. The affected area of the stomach was found to be hard, and formed a mass, simulating malignancy, and often causing either pyloric obstruction or hourglass contracture. There was much thickening and scar tissue. If the lesion involved the pyloric end of the stomach, it stopped short at the duodenum.

Pathological examination revealed multiple, usually shallow ulcerations, often inflammatory, with markedly thickened, fibrous walls. Microscopically, there was dense lymphocytic infiltration on the mucous surface, as well as perivascular lymphocyte and plasma cell infiltration, and marked perigastritis. There was no evidence of tuberculosis.

There was nothing unusual in the types of operation done in these cases. All the patients received treatment for syphilis before operation. The significant point is that, in three of the cases, the lesion was not suspected of being syphilitic until this was indicated by the operative and pathologic findings, and the diagnosis assured by positive Wassermann reactions. In two cases the findings at operation established the previous suspicion of syphilis. Hence, in cases of multiple gastric ulcers which present the gross characteristics already mentioned, a careful microscopic examination, and an investigation for syphilis should be made, lest this condition be overlooked.

DISCUSSION

Many types of operations were used in this series of cases, including simple gastroenterostomy in the case of several perforating ulcers on the posterior wall of the stomach, pyloroplasty, and other plastic operations in the earlier years, and more recently resection of part of the stomach. Although we may not agree with Finsterer and others in the radical measures for a single ulcer, in the case of multiple

ulcerations a resection, including the entire ulcerated area, seems best. The various operations performed in this series are shown in Table I. It will be noted that some form of resection was performed in considerably more than half the cases.

TABLE I

Cautery excision or destruction, and pyloroplasty	3
Pyloroplasty	3
	87

The results of operation are shown in Table II. Three patients could not be traced, and eleven were operated on too recently to permit the determination of results. The hospital mortality for the series was notably low, three and four tenths per cent., compared with a mortality of four and five tenths per cent. for the total of 1,228 gastric ulcers operated on during the same decade. Of the three deaths, one was due to pneumonia, one to pulmonary embolism, and one to hemorrhage from seven acute ulcers.

Good or fair results, but later trouble	7
Not located or traced, or result not known	3
Good, but the patient died in one to three months from accident or otherwise	3
	87

Failures.—The one case in which the results are classified as poor was that of a woman who had had a sleeve resection for marked hourglass deformity. She improved for a very short time, but since then has had a good deal of discomfort. In one of the cases listed as a failure, a carcinomatous ulcer was associated with simple ulcers. Although a Pólya resection was performed, the patient returned to the Clinic in five months with recurrent carcinoma of the stomach, and died soon after.

The second of the failures was a case in which several ulcers on the posterior wall had perforated. A gastroduodenostomy was performed, but the symptoms soon returned and became as severe as before. Subsequently the patient had a severe gastric hemorrhage, and two years later died, the cause not being known.

The third case was one in which an anterior Pólya resection had been performed. The patient reported one and one half years later that he had not obtained relief, that he had the same symptoms as before, and was in poor condition.

Temporary Good Results Followed by Recurrence.—Of the cases in which partial or complete relief was obtained for a variable period, with later gastric symptoms, there were definite recurrences in two. In one, several gastric ulcers had been excised by cautery and a gastroduodenostomy performed. The patient was completely relieved for one year, and then had a recurrence of symptoms. He was again operated on recently, and eight ulcers were found in the stomach. A Billroth 1 reaction was performed. The other case was that of a woman who had had a knife excision of multiple gastric ulcers, combined with a posterior gastroenterostomy. The result was good for a year, then the symptoms returned. On exploration, two gastric ulcers and a gastrojejunal ulcer were found. A posterior Pólya resection was performed, and the patient is now in excellent health.

In the other instances, various factors were responsible for the return of symptoms. One patient had had an anterior gastroenterostomy for ulcers on the lesser curvature and posterior wall. After a year of relief, he developed symptoms of ulcer, and died from acute perforation. It is questionable whether this was a recurrence, or a reactivation of the ulcers, which had not been removed. Another woman had had a plastic operation and posterior gastroenterostomy for an hourglass deformity from a perforating ulcer. After a period of complete relief, she was operated on elsewhere for a recurrence of the hourglass deformity. Still another patient who had had a Billroth 1 resection, and had been relieved for a year, was reoperated on elsewhere for what was said to be an obstruction to the outlet, the cause not being mentioned. Another man who had obtained relief following excision of ulcers, and a plastic operation, returned recently with symptoms of obstruction, and a posterior gastroenterostomy was performed.

The seventh patient returned one and one half years after gastroenterostomy had been performed, and operation revealed chronic obstruction of the proximal loop of jejunum, due to extensive adhesions. These were separated, and one gastric ulcer excised. The results are now reported as excellent.

Iodotherapy of Pernicious Anemia. — Gottfried Holler (*Wiener klinische Wochenschrift,* June 26, 1924) considers pernicious anemia as a hemolytic anemia, in which the hemolysin is formed by the primary disease and the dysfunction of an organ with increased endocrine functions. He, therefore, recommends iodotherapy in pernicious anemia (if possible following a splenectomy) in the following way:

The patients are given three times three to three times five drops of a five per cent. solution of potassium iodide internally for a long time (even for years). It may also be well to administer thyroid gland preparations at the same time for a while. A simultaneous carefully conducted course of arsenic seems also to be of considerable value. He emphasizes the fact that an acute (early) result of the iodotherapy should not be expected, as for this purpose arsenic or, better yet, a transfusion of blood is more serviceable. The value of iodotherapy lies in the lasting effect.

Pyloric Stenosis and Pylorospasm

A. J. SCOTT, Jr., M.D.
Los Angeles, California

These two conditions are separate entities, but resemble each other clinically. Certain cases of stenosis are so mild and so amenable to treatment that they may be classed as spasm unless a definite tumor is found. These conditions are so often unrecognized or thought to be some other condition that it seems appropriate to consider the cases we have seen either in private practice or in the clinic[1] in the past two years, and discuss the outstanding features.

Theories as to etiology are not discussed except to mention that the condition is probably antenatal as evidenced by cases found in prematurely born and stillborn infants. The pyloric muscle begins to develop about the third month of fetal life and the size is proportionate to the age of the infant.

Age.—Usually from the third to sixth week. Our cases of stenosis were eight in number and the age incidence from four weeks to two months, while the cases of spasm were seven in number and the ages ranged from four weeks to three months.

Sex.—Of the stenosis cases there were four females and four males, and of the spasm cases four were males and three females. This shows the condition to be about equally divided.

The figures of Still, who reported 247 cases, showed thirty-seven females and 210 males. Also he reported the majority of his cases as occurring in the firstborn. Our stenosis cases were six first born, one second and one third, and the spasm cases were four first and three second born. No especial notes were made as to parental age, but all were young excepting in one case and the general health was normal.

Histopathology.—Wollstein has studied these cases particularly and found no changes in the mucosa. The changes are limited to the submucosa and circular muscular fibres. There are no inflammatory changes. The vomiting is purely mechanical. The submucosa is edematous and wider than usual. The circular coat is two to three times wider than normal, due to the large amount of muscle tissue. There is no increase in the connective tissue between the cells. The serosa is normal. The average thickness of the circular coat is one and six tenths mm. and the average length of the pylorus one and five tenths cm. In stenosis the average width of the circular coat is four and four tenths mm., while the average length is three cm.

Symptoms.—Certain features stand out prominently and should make one suspect an obstruction of some sort. Vomiting is the first and most pronounced symptom and the one which usually causes the mother to go to the physician. It is essential that a careful history be taken as to the kind of food, the feeding intervals, the length of time at feedings, and whether the vomiting is merely a regurgitation or of a projectile type. Much may be learned from this history. The next step is to strip the child and examine the bared abdomen in a good light. I prefer the light coming from above or from the foot of the patient. If there is an obstruction, even slight, there is a fullness of the upper abdomen, while below the navel it is more flat. If there is food or water in the stomach, it is easy to see peristalsis from the left to the right across the abdomen, just above, or at the level of the umbilicus. The waves are quite characteristic and are not noted in the normal abdomen. If the stomach is empty peristalsis is not noted or only faintly after prolonged watching. The tumor is not always palpable; some assert, however, that all cases of stenosis have a palpable tumor. It may be found more constantly if the condition has gone on for some time. It is high up, just to the right of the midline of the abdomen, and usually behind the edge of the liver. Palpating gently and persistently after food intake and while peristalsis is going on, at the end of a wave you may be able to feel a little knot, not larger than a small olive, and easily overlooked unless you are watching for it. The thinness of the abdomen in these cases, especially where there is emaciation, makes this process easier than in the normal well nourished infant. The stool found in true stenosis is a starvation stool, brownish and thin, while in spasm there is more substance to it. These are the conditions where physics are used so extensively due to a mistaken idea of the treatment of the constipation, which is due not to the inability of the bowels to move, but to the lack of intestinal contents.

DIFFERENTIAL DIAGNOSIS

So far, the two conditions of spasm and stenosis have been considered together, and now come the differential points. It is an easy matter to use barium and the x ray to make diagnosis. In stenosis, the barium does not pass out except in small amounts in the first four hours, the appearance of the stomach being that of a round shadow with no apparent outlet except at the cardia. In spasm, at the end of four hours a large part of the barium has passed through the pylorus and may be seen to pass through intermittently. However, it is not necessary to have the x ray for diagnosis. The therapeutic test is quite satisfactory, although Haas claims that all cases of stenosis are merely advanced stages of spasm and may be treated medically with recovery. This statement is not in accord with our experience and that of others. The experience of Strauss, that the spasm cases do not have that cartilaginous type of tumor which is sharply marked when cut in two, seems also to throw doubt on the theory. We have found that if the infant does not respond promptly to treatment by proper medication and diet, and if x ray is not available, open surgical treatment is necessary. In all our cases of stenosis even though the tumor was not always definitely palpable before operation it was present when the abdomen was opened. The nutrition, in all cases of stenosis seen

[1]Anita M. Baldwin Hospital for Babies.

shortly after the initial vomiting, was fairly good, though there was a gradual loss of weight, which usually was the same as at birth or slightly lower. This was not so marked in the true spasm cases, where there was a slight increase over the birth weight.

PROGNOSIS

Goldbloom and Spence in their studies found that twenty per cent. loss of the highest weight was the maximum that an infant could lose and still recover, with proper surgical interference. The mortality of bottle fed babies is three times that of the breast fed. The mortality is less in cases which have lasted four weeks or less, than in those which have lasted over four weeks. Therefore the earlier the diagnosis and the institution of proper treatment the better the prognosis. If an infant does not respond to medical treatment within seventy-two hours or less from the time it is first seen by us we advise immediate operation.

TREATMENT

This may be divided into two types, medical and surgical. The medical treatment is primarily for spasm cases or mild stenosis cases. We use one to five drops of a one to one thousandth atropine solution made up fresh, and give it one half hour before feedings in one teaspoonful warm water, or one one thousandth grain of atropine hypodermically fifteen minutes before feedings.

If the infant is breast fed we put it to the breast for five minutes and then place it in an upright position so that gases may be expelled easily, and regurgitation may not be induced. If the infant keeps the food down, as is sometimes the case, we continue this treatment. Points that should be emphasized are that no abdominal binder should be on the infant, but everything free to avoid any pressure over the stomach, or epigastrium; that the infant should not be handled for at least two hours after feedings; and the feedings should be four hours apart.

If the liquid diet is not retained after three or four attempts we institute thick cereal feedings. Our formula is as follows: skim milk ten oz., water eleven oz., farina or cream of wheat six to eight level tablespoonfuls and dextrimaltose, three level tablespoonfuls. The larger amount of cereal is used when we use breast milk in addition to cow's milk, making the addition as will be told later. The mixture is cooked for one and one half hours in a double boiler and should be thick enough to stick to the spoon when inverted. This is Sauer's method. When we add breast milk we have the mother express it directly into a sterile container and mix about one ounce of this with three ounces of thick cereal. In this manner, no cooking is done to the breast milk and the food is better. This mixture is fed through a large nipple which has the hole cut about one quarter inch in diameter and is pressed through with a spoon. The material may be kept warm and fairly soft by keeping in a dish of hot water, while feeding. The feeding periods are every four hours.

We have not used the stomach washings before feedings, nor even once a day as some advocate, although it is usually recommended, but we believe that the less handling these patients have and the less irritation of the gastric mucosa by mechanical means the better results are obtained.

If medical treatment is not satisfactory and the food is regurgitated, the time has come when surgery is indicated, particularly if the weight remains stationary or there is a loss, but do not consider surgery a last resort. If the patient presents the typical findings when first seen, do not wait to try medical treatment and lose time but operate as a life saving procedure. If the case is not appropriate for medical care and the technic correct, results are satisfactory. Our surgeons use the Rammstedt modification of the Fredet method. There is no other method to be considered. Our mortality was one case which was moribund at the time of operation. We wash the stomach out before operation. Ether anesthesia is used and just before closing the abdomen thirty c.c. of normal salt solution is placed in the peritoneal cavity. The patients are kept warm, quiet, and nothing given by mouth until two hours postoperative. Then one dram of water is given every hour until the sixth hour, then one dram of mother's milk and one dram of water every two hours for twenty-four hours. At the end of twenty-four hours, if there is no vomiting, we give two to four drams of mother's milk undiluted every three hours and at the end of forty-eight hours, one ounce of mother's milk every three hours, with water between. By the third day we give full feedings provided there is no vomiting. Where the mother is nursing, she holds the infant on a pillow and feeds directly at the breast. The stitches are removed on the seventh day and the infant sent home on the tenth.

The following case histories will illustrate some of these points:

STENOSIS

Case I.—D., August 29, 1922. Consultation with Dr. Bewley. Age five weeks, female. Vomiting since birth which had become more intense. Stools were green and constipated. The patient was extremely emaciated and dehydrated. Peristalsis was visible. Thick cereal feedings were advised, also atropine solution. At the end of twenty-four hours, the child was removed to the hospital and 160 c.c. of normal salt solution given intraperitoneally. The thick feedings were retained. On August 31st, it was considered advisable to operate. While on the operating table the child was given five per cent. glucose, ten c.c. intramuscularly and ten c.c. subcutaneously. It was put to bed in good condition. The child made an uneventful recovery and was discharged at the end of a week.

Case II.—March 18, 1922. L., a female, was brought in from Lancaster, at the age of two months. Birth weight ten pounds. Had vomited for two weeks. The child was the youngest of three. Had had a normal delivery. The first child was still born. Never had breast feedings because the mother was advised not to nurse it as she was told that she had tuberculosis. The baby had been fed on Eagle Brand condensed milk and weighed ten pounds. The heart and lungs were normal. There was visible peristalsis from left to right with palpable tumor in upper right quadrant; marked dehydration, stools green and constipated, no blood. A simple dryco mixture was tried but regurgitated. On the 19th,

the child was removed to the hospital. Barium mixture was given, but little passed through the pylorus. At operation the child was in only fair condition. The postoperative vomiting persisted in spite of stomach washings and atropine solution. On March 25th, the abdominal sutures broke and the wound opened. It was closed quickly, but vomiting persisted and the patient died March 29th, of acute peritonitis. Autopsy showed a small perforation at the duodenal end of the incision and slight peritonitis. This was the only death we had.

CASE III.—K., male, referred by Dr. Flint on November 16, 1922, at the age of six and one half weeks. The baby started vomiting three weeks before. This was of the projectile type, after nearly every feeding and if he held one meal down it would be expelled at the next feeding. Sometimes this vomiting occurred as soon as feeding had finished.

This was a first child. The labor lasted forty-eight hours, instrumental delivery. Birth weight was six pounds. Breast fed every two and one half hours. Stools at first were yellow, but had been green for three weeks and extremely constipated. The heart and lungs were negative. Skin was in fair condition, no dehydration. Abdomen showed visible peristalsis from left to right; no tumor was palpable. Atropine solution was given but vomiting persisted. The patient was operated on November 17th, and on November 29th the weight was seven pounds ten and one half ounces. He was getting breast feedings right along. On March 12, 1923, the weight was thirteen pounds eight ounces.

CASE IV.—E. T., October 17, 1922. Consultation with Dr. Armstrong. There had been projectile vomiting for three days, with constipated green stools. The patient was a female, aged four weeks. A first child, and had had a normal delivery. The mother was asthmatic. The birth weight was six pounds six ounces.

The present weight was five pounds fifteen ounces. Nutrition fair, good tissue turgor, some depression of anterior fontanelle. The heart and lungs were negative. There was visible peristalsis from left to right, but no definite tumor mass palpable, projectile vomiting. Atropine solution was advised for twenty-four hours and a continuance of breast feedings. After forty-eight hours because of persistent vomiting and weight loss an operation was performed. Breast feedings were continued and the case dismissed October 28th. November 9th, three weeks after operation, the weight was seven pounds one ounce and the patient was doing well. Since then the condition of the child has progressed normally.

PYLOROSPASM

CASE I.—W. T., December 30, 1921. Male, age three months, normal delivery, second child, breast fed one month, then on modified cow's milk. Birth weight eight pounds. The complaint was colic and vomiting.

Examination: The chest findings were negative. There was visible gastric peristalsis. The weight was ten pounds. The stools were constipated.

On January 1, 1922, atropine solution was begun, the liquid formula being continued, but the vomiting persisted so the child was put on a thick cereal mixture plus atropine. The stools became better, but a dermatitis developed, probably from the excess starch in the feedings. He vomited water or any liquid for over a month after starting treatment. Recovery finally ensued. No x rays were taken.

CASE II.—F. B., January 9, 1922. The complaint was "spitting up." The patient was a male, aged two months. Birth weight eight pounds eight ounces. Was on breast feedings up to January 1st, and gained up to ten pounds two ounces. On account of mastitis in the mother, the child was weaned and on January 9th the weight was down to nine pounds four ounces. The stools were a pasty yellow. There was some spitting up. He was put on a wheat flour and water mixture. On January 14th the weight was nine pounds fifteen ounces. The vomiting had become persistent and the stools were constipated. It was advised to continue the same feeding, but on January 19th it was necessary to give thick cereal feedings and atropine solution. Visible peristalsis was not present and no x rays were taken, the only symptom being the persistent projectile vomiting. This food was retained and we gradually cut it down and increased the milk and water mixture. On December 18, 1922, his weight was twenty-six pounds fourteen ounces. There was always a question as to whether this was a true pyloroplasm, but clinically it resembled these cases in many ways. There was undoubtedly a neurotic basis back of the vomiting in this case as in spasm.

CASE III.—Baby R. K., July, 1922. There had been persistent vomiting, colic, brownish stool, somewhat foamy. Duration seventy-two hours. The patient was a female, first child, aged five weeks (referred by Dr. Guidinger of San Pedro). The child was well nourished, temperature 98.6°, heart and lungs were negative. She had on a tight abdominal binder because of a small umbilical hernia. Visible gastric peristalsis was noted. Removing the binder and the use of atropine relieved the vomiting. This baby might easily have been weaned if no history had been taken, and is reported here especially for this purpose.

The mother was neurotic. The tight abdominal binder and probably an increased tension of the infant's nerves, might in the end have been one of the factors back of pylorospasm. This child was seen when she was one year and two weeks old and was found to weigh only fifteen pounds, and was nursed up to her first birthday. She was still high strung and the probabilities are she will later be a subject for the gastroenterologist, as every time she has a little infection or cuts a tooth, she has a marked digestive upset.

CASE IV.—T., September 27, 1922. There had been projectile vomiting for a week. The patient was a male, aged four weeks, second child, normal delivery, breast fed until two days before we saw him. Because of persistent vomiting the baby was put on modified cow's milk. The birth weight was unknown.

The patient was well nourished. It was not weighed this day as there were no scales at the home. The chest was negative. The abdomen showed visible gastric peristalsis after taking food, but no tumor palpable. The stool was greenish yellow with

mucus. Atropine solution was ordered, one half hour before every feeding. On September 30th his weight was nine pounds six ounces, although vomiting persisted. Fluoroscopic examination and plates showed a normal sized stomach which emptied intermittently, apparently a spasm, as in three hours and one half, part of the meal was still in the stomach. The atropine solution and breast feedings were continued. On October 13, 1922, the mother reported by letter, "Glad to say baby is fine and hasn't spit up any since at your office. Haven't given any drops for over one week and is gaining right along." Recovery followed.

CONCLUSIONS

1. There are two definite conditions, spasm and stenosis.
2. Spasm is apparently a nervous condition, while stenosis is a true hypertrophy.
3. It may be and probably is possible to have both conditions together.
4. Spasm is strictly a medical condition, while stenosis is surgical.
5. The Fredt-Rammstedt procedure is the operation of choice.
6. Atropine solution and the thick cereal mixture are specific in the spasm cases.
7. Do not delay operation in stenosis cases where there is marked dehydration, longer than necessary to get fluid into the peritoneal cavity and have some absorbed.
8. Do not wean the baby because it is vomiting mother's milk, but strip it and examine the abdomen. Palpate for a tumor at the pylorus.
9. Do not physic the infant for constipation, especially when vomiting, until you have examined the naked abdomen.

Perforated, Intrathoracic, Hourglass Stomach (Eventration)*

J. RUSSELL VERBRYCKE, JR., M.D.
Washington, D. C.

The case about to be reported is unique in that it presents a combination of a perforated ulcer in an hourglass stomach with an eventration of the diaphragm, the latter condition, of itself, being of sufficient rarity as to be noteworthy.

Eventration of the diaphragm is an abnormal elevation of one side of the diaphragm, without break in continuity of structure. Only about one hundred and twenty cases are on record but, since I am shortly to publish a quite complete paper on the subject with report of seven cases, the present report will deal more with the treatment of the ulcer under such difficulties as were presented.

CASE REPORT

CASE.—Mr. A. W., aged forty-five, a merchant, was referred by Dr. Sam Maphis, of Warrenton, Va., October 19, 1923. The patient's mother and several brothers and sisters had stomach trouble but otherwise his family history was negative. His health had been excellent all his life except for constipation, which started when a young man, and periodical stomach attacks for twenty or twenty-five years. These periodical upsets were rather typically those of peptic ulcer as there would be pain in the epigastrium about an hour after meals, relieved by soda. He had not tried the effect of food. Bloating and fullness accompanied the pain. Six years previously he had a severe gastric hemorrhage and after recovering from the shock a posterior gastroenterostomy had been performed. The surgeon made no note of any abnormality of the diaphragm or position of the stomach at the time.

He stated he had derived no real benefit from the operation, except that there had been no recurrence of the hemorrhage, and that his recurrent dyspepsia occurred just the same. About a year before he had a sudden attack of severe pain in the epigastrium and left lower chest, necessitating the use of morphine for several days. This was diagnosed as pleurisy by a gastroenterologist, but looking backward with the light gained by future study, I am convinced that this was a pinhole perforation which was shortly sealed up.

During the last six months he had been experiencing more and more trouble with his stomach. Pain had become more and more continuous and soda had lost some of its power of relief. Three days before our examination he took a rather strong laxative to relieve constipation of several days. Shortly thereafter he began to vomit and retched terribly. This gave him a feeling as if something had torn loose in the upper left abdomen and was followed by agonizing pain in the upper abdomen, necessitating large amounts of morphine for the three days before he came for examination. Pain was steady and severe but not colicky in character.

The patient was healthy looking and well built. The skin was flushed. The tongue was dry and moderately coated. Pulse was 100 and temperature was slightly elevated but otherwise examination was negative. There was no localized tenderness and no rigidity. Hemoglobin was 86 per cent. and leucocytes 18,600. Uranalysis and testmeal analysis were both normal.

On fluoroscopic examination I was amazed to see the stomach in the chest opposite the heart so he was sent to Christie, Groover and Merritt for a complete fluoroscopic and film examination. The first was done at their office and he was then taken to Garfield Memorial Hospital, put to bed, and the examination completed there.

Examination of the chest showed no evidence of the presence of disease of the lungs. The heart and great vessels appeared normal in size and position.

*Read before the Medical Society of the District of Columbia, May 21, 1924.

There was marked eventration of the diaphragm on the left side; the diaphragm extended up to the level of the third rib in front and the seventh rib behind. Both the splenic flexure of the colon and the fundus of the stomach were high up against the dome of the diaphragm. There was a distinct hourglass condition of the stomach with a six hour residue in the upper loculus. The entire pyloric half of the stomach showed extensive deformity. The gastroenterostomy showed well and appeared to be functioning. There were a number of very small circular shadows between the stomach and the spine at the site of the hourglass. They were possibly particles of barium in a large accessory pocket. The röntgen diagnosis pointed definitely to the presence of an extensive organic lesion of the stomach, probably a perforated ulcer, with extensive adhesions.

It was evident that he had to be operated upon for the subacute perforation which might become unsealed again at any time, particularly since he was rather difficult to manage. The position of the stomach was so high in the chest (Fig. 1), that it was problematical as to what could be done. It explained the absence of tenderness in the abdomen and the absence of rigidity since the general peritoneal cavity had evidently not been soiled before adhesions sealed the opening.

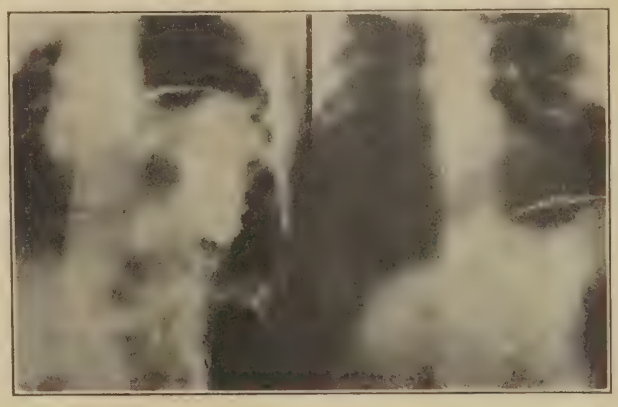

FIG. 1. FIG. 2.

FIG. 1.—Before operation. Note upper sac of hourglass opposite heart shadow with nearly complete obstruction. Line of diaphragm retouched.

FIG. 2.—Four months after operation. Note disappearance of hourglass with perfect functioning through the old gastrojejunostomy. Diaphragm several inches lower. Line of diaphragm retouched.

The abdomen was opened through a left rectus incision, October 23, 1923, with L. H. Reichelderfer and E. L. Morgan assisting. There was little muscle and poor differentiation of the abdominal layers which were all more or less fused, probably from his old operation as the incision was only three fourths inch from the scar. The omentum was adherent to the anterior abdominal wall. Adhesions were divided so that good exposure was finally obtained, the incision reaching to the xyphoid.

When the abdomen was opened the left diaphragm became convex, from below, instead of concave and flopped downward. It was of a pale grey color like a piece of wet blue blotting paper, thin and with apparently no tone whatever, as each respiration caused it to flap back and forth with a perceptible noise. Examination showed no rent in the diaphragm so that the condition was one of eventration and not hernia, although the part about the esophageal opening could be invaginated with the weakest spot about one and a half inches in diameter with a distinct ring about the circumference.

Adhesions from the left lobe of the liver to the diaphragm and stomach had first to be divided. Then the stomach which was adherent to the diaphragm was gradually freed to such an extent that it could be brought several inches lower. Even then the position was high under the ribs. On the posterior wall and lesser curvature, quite near the cardia was a large adherent mass consisting of indurated ulcer and inflammatory tissue walling in the perforation. It felt but did not look like a malignant growth.

A distinct hourglass contraction, as shown by the radiographs, was present at the site of the ulcer, but on the anterior surface of the stomach there was a bridge of healthy uninvolved tissue. The old gastroenterostomy was perfectly normal but being in the lower sac it was useless.

It was manifestly impossible to do a resection of any kind with any prospect of being able to close the opening. A gastrogastrostomy could not easily be done and even an attempt at cautery destruction was not thought advisable because of the extreme inaccessibility of the lesion. The perforated area was whipped over and infolded as much as possible and then covered with omentum. Because of the little strip of healthy tissue on the anterior surface and the knowledge that much of organic obstruction is due to edema and spasm resultant from the inflammatory process, it was decided that the safest thing to do would be to let the closure of the perforation and the change in position of the stomach, which had been accomplished, suffice and to hope that strict medical treatment would remove at least a part of the hourglass. The abdomen was closed and the patient left the table in good condition.

There were no postoperative complications. He was kept in a semiupright position continuously from the time of the operation to get what benefit could be obtained from gravity. A strict medical cure for ulcer was instituted and kept up for three weeks after which time he was allowed to get up but was placed indefinitely on a soft, selected diet, with alkalies fifteen minutes and an hour after each feeding, and small inbetween meals consisting of milk or crackers.

The wisdom of the conservatism in the treatment of this case is shown by the fact that fluoroscopic examination on discharge from the hospital showed a beautiful wide opening where the hourglass had been and food was passing freely to the gastroenterostomy opening which was functioning perfectly. The patient since that time has had some pain on several occasions but the result may be said to be good.

An x ray examination, which was made four months later (Fig. 2), showed that no marked hourglass stomach and no obstruction were present, but the most gratifying feature was that the diaphragm was about four inches lower than it was before the operation was performed.

THE ROCHAMBEAU.

A Phase of Hernia Too Little Emphasized

CHARLES EVERETT HAINES, M.D.
New Rochelle, N. Y.

That an oblique inguinal hernia which is just appearing through the internal inguinal ring may cause pain is a fact too seldom recorded in writings on the subject of hernia. Likewise, this fact is not stressed frequently nor emphatically enough in teaching the subject. It is, nevertheless, of considerable importance, especially because the symptoms of such a hernia may simulate those of chronic appendicitis.

Now, in the abundant literature dealing with the number of mistakes in diagnosis of chronic appendicitis for which appendectomies have been done the rate of failure is set as high as from thirty to sixty. These failures are a constant source of chagrin to both surgeon and physician, and consequently, writings are not lacking in explanations and in pleas for more careful examination of the patient.

Many other, better diagnoses have, from time to time, been suggested as possibilities and have been thoroughly discussed except one—oblique inguinal hernia. This condition, while receiving mention now and then it is true, has not been discussed as thoroughly as is warranted by its importance.

The pain or discomfort of a beginning oblique inguinal hernia is usually located over the internal ring. This pain is frequently increased by any movement of the trunk on the pelvis or by coughing; while it is usually relieved by lying on the back. There may be nausea due, apparently, to a reflex stimulation from the knuckle of intestine or peritoneum which is caught in the ring. In an uncomplicated case there are no other symptoms.

In all cases of suspected beginning oblique inguinal hernia, the patient should be examined in the erect posture. The area over the internal ring should be carefully inspected and palpated while the patient is coughing as well as during quiet respiration. A slight bulge may sometimes be made out over the internal ring in slender patients while they are coughing. This finding, however, is rare. The most common finding is to have the patient say that the pain from coughing does not develop when the thumb is held firmly on the skin over the internal ring, which, together with the history of pain in the local area, is sufficient evidence upon which to base a diagnosis of hernia.

When this hernia is on the right side the symptoms may and frequently do simulate a chronic appendicitis thus unfortunately too often leading to an incorrect diagnosis.

Considering the matter in this light, even more operations for chronic appendicitis are uncalled for, doubtless, than writers on the subject have hitherto suspected. Also there are doubtless too many unfortunate patients who continue to suffer but are suspected of being hypochondriacs once the appendix is out and further examination fails to elicit the true cause of the trouble.

In every case of socalled chronic appendicitis, therefore, a careful history should be taken and examination made with special reference to the exact location of the pain, in order to eliminate the possibility that the trouble is at the internal inguinal ring. Likewise, in every case of lower quadrant pain or discomfort which cannot be satisfactorily explained by some other pathology, a beginning hernia should be excluded.

It should also be borne in mind that the hernia may remain at the internal ring, causing pain or discomfort for many weeks or perhaps months, as in the first case cited below.

The Torek (1) method of repair would seem to be the method of choice in dealing with a beginning oblique inguinal hernia in the male. Any other good method is satisfactory in the female as a consideration of the anatomical difference in the contents of the inguinal canal will readily show. Unless the vas and vessels are separated, according to the Torek method, a small hernia may be entirely overlooked, for it has been found that all of these herniae appear at the internal ring within the substance of the cord between the vessels above and the vas below (1). It seems in fact that only by obliterating the potential opening between the vas and vessels can a small hernia be cured. This is accomplished by suturing the internal oblique and transversalis muscles and transversalis fascia to Poupart's ligament with two or more number two chromic catgut sutures placed between the vas and vessels to keep them apart.

Case I.—J. K., a man, married, a piano polisher, thirty-three years of age, of Irish extraction. He complained of slight pain and discomfort in the right lower quadrant of the abdomen especially when he bent forward or lifted heavy objects. This was first noticed about fourteen months before his admission to the hospital. The pain was apparently relieved on lying down. A supposedly thorough examination was made, including an x ray series of the gastrointestinal and urinary tracts; the patient was also cystoscoped and the ureters catheterized. No cause was found for the pain.

In consideration of a history of many previous hospital admissions he was suspected of being a hypochondriac and finally discharged from the hospital. Just before he was ready to leave for home a palpable oblique inguinal hernia developed. This was repaired by the Torek method. One year later the patient reported that there had been no recurrence of the pain or discomfort.

Case II.—I. N., a woman, single, a factory worker, eighteen years of age. She complained of a dull ache in the right lower quadrant of the abdomen. This was first noticed about two months before her admission to the hospital. She suffered pain when she stood but not when she lay down. There was neither nausea nor vomiting, nor were there urinary symptoms. The bowels were regular. Physical examination showed that the pain was localized over the internal inguinal ring on the right side. This pain was most severe when the patient was standing

or when she coughed. If, however, the thumb was held firmly over the internal ring coughing caused no pain. An oblique inguinal hernia was the diagnosis in this case and proved at operation by finding a small hernia at the internal ring. One year later the patient reported that there had been no recurrence of the pain.

SUMMARY AND CONCLUSIONS

1. It is suggested that some cases diagnosed as chronic appendicitis and especially those which are not benefited by appendectomy may be cases of beginning oblique inguinal hernia.

2. Sufficient emphasis has not been placed hitherto upon the symptom of pain or discomfort in the diagnosis of beginning oblique inguinal hernia. This pathology should be excluded in all cases of lower abdominal pain not readily explained on some other basis.

3. A thorough history and great care in physical examination is often necessary to establish a diagnosis of beginning oblique inguinal hernia.

4. The Torek method of repair is advocated in cases of oblique inguinal hernia in males.

5 ANDERSON STREET.

Hypopancreorrhea (Hypopancrehea)*

ANTHONY BASSLER, M.D.
New York

In diagnosing disease of the liver and pancreas many difficulties are met with. This is particularly true of the pancreas. This important gland is sufficiently remote to shield it from examination, but not from injury, and its secretion is poured into such an inaccessible region of the alimentary canal that for a long time the study has been a puzzle to the physiologist and baffling to the physician. In the middle of the last century Sir Thomas Watson in his lectures expressed the following opinion: "It may seem a slight to the pancreas to pass it over without noticing the diseases to which it is subject but really these diseases appear to be but few; and they do not signify their existence by any plain or intelligible signs." Many of the premier men of medicine since then have expressed practically the same view. There are today others who hold to a more optimistic viewpoint which, nevertheless, may still be expressed in the words of Wardell who in 1871 wrote: "No symptoms are pathognomonic of pancreatic disease; an assemblage of symptoms indicates the probability of its lesion."

It is true that we have learned to recognize in fat necrosis a sign indicative of certain lesions of the gland; but this is only manifest with the abdomen opened and lends us no help at the bedside. One other sign has been claimed as significant since Kunzmann's work of a hundred years ago, namely true steatorrhea. It must be apparent, however, to anyone who has had sufficient experience in the origin of obscure abdominal troubles that if we keep the pancreas in mind only disorders of this organ can explain some of the cases that are seen.

Hypopancreorrheic states may be classified as far as our limited knowledge has gone as follows:

FUNCTIONAL

Severe emotional depression (transitory)
Marked adynamic disease
Reflex from cholelithiasis
Congestion from cholelithiasis
Arteriosclerosis
Pressure of large cysts
Causes unknown

PRIMARY ORGANIC

Chronic intralobular pancreatitis
Combined intralobular and interlobular pancreatitis
Hemochromatosis (diabetes mellitus) bronzed diabetes
Congestion of head of the pancreas causing sclerosis
Acute and subacute pancreatitis
Abscess of pancreas
Multiple cysts
Fatty and hypertrophic degeneration (islands of Langerhans) diabetes
Hyaline degeneration of whole gland

SECONDARY ORGANIC

Carcinoma of the pancreas (head)
Syphilis of the pancreas (head)
Tuberculosis of the pancreas (head)
Chronic duodenitis (ascending infection)
Chronic infectious galltract disease
Sarcoma of the pancreas
Cirrhosis of liver
Addison's disease
Obstruction of duct of Wirsung
Pancreatic calculi (multiple)
Achylia

In an able lecture on the subject in 1920 Sir Archibald Garrod presented the indications at our disposal to fall into three main groups as follows:

PANCREATIC SIGNS AND TESTS

Physical Signs and Symbols	*Defects of External Secretion*	*Defects of Internal Secretion*
Aspect	Steatorrhoea	Glycosuria
Tumor	Fatty stools	Lowered sugar tolerance
Pain	Creatorrhea	Cammidge's tests
Tenderness	Impaired casein digestion	
Cyanosis		
Vomiting		
Constipation	Duodenal sound	
Diarrhea	Einhorn's method

ciate with lesions of the pancreas. For instance, the diagnosis of carcinoma of the head of the gland is often correctly made upon clinical evidence and in instances of bronzed diabetes with enlarged cirrhotic liver and peculiar pigmentation of the skin, the pancreas is always implicated.

The physical signs and symptoms of pancreatic disease are best seen in cases of acute pancreatitis, although the large cysts which occasionally spring from the pancreas produce the more conspicuous swellings and it is with carcinoma that the pressure signs are most manifest. The purpose of this article is not to deal with the diagnosis of acute pancreatitis, difficult though it often is, but rather to present data on the still more difficult diagnosis, namely, that of the more chronic cases. In these the tumor of the grossly enlarged pancreas in the upper abdomen and differentiation between the chronic form of trouble and intestinal obstruction never arise. Still there are instances of acute disorder of the pancreas in which recovery ensues without any special treatment, surgical or medical, and in which the factor of continuous or paroxysmal pain and quite alarming symptoms closely approximate those present in acute hemorrhagic pancreatitis. In these the characteristic back pains and even some degree of vomiting may exist. Perhaps one is called upon to make no more difficult conclusion than in these obscure acute cases of recoverable pancreatic disorders and that of hemorrhagic necrosis that justify a fatal prognosis. The best of opinion here is wrapped in doubt and a few hours' observation of the case is essential for any degree of wise conclusion. Whether these belong to the type designated by Curtin as catarrhal pancreatitis with viscid contents in the larger ducts, desquamated columnar cells and the acini considerably dilated, or are forms of ascending infections of low degree, is hard to decree at this time. Certainly some of them, even though there are no products of inflammation, such as leucocytes or fibrin, will go on to abscess formation. Of value here is the history of a cholelithiasis which may help one in prompt decision of surgery. But in the absence of these, the marked symptoms of pain not being relieved by opiates, cyanosis, vomiting and those that simulate intestinal obstruction, may warrant conservatism.

Chronic pancreatitis and deficient states of pancreatic function, the main subject of this article, up to quite recently was difficult to recognize during life. One of the main reasons for this was the fact that as far as we were able to judge from symptoms, or rather from the absence of them, and any of the tests, nothing was definite. In many instances a considerable portion of the parenchyma is undestroyed and the gland is capable of functioning sufficiently without symptoms of any disturbance of digestion or glycosuria. What makes it still more difficult is that many of these instances follow or accompany grave disturbances of the stomach, duodenum or bile passages in which the symptoms of the primary disorder predominate and hinder recognition of the pancreatic disorder.

Among those that may be worked out from study of the acute cases and a few of those of frank pancreatitis are pain in the epigastric region, perhaps between the scapulæ or in the upper dorsal. This may be acute, continuous or paroxysmal or may be of the dull and long continued type.

Of the pressure symptoms of jaundice (noticed in its extreme degree in carcinoma of the head of the pancreas) with acholic stools and characteristic urine none is more conspicuous. One may safely believe with Osler and Sir Mayo Robson that jaundice may be present in the chronic case perhaps not steadily and only slight and transitory coming on from swelling of the head of the gland. One can prove this best in mumps in which a metastasis in the organ occurs. Should it be present the pancreas at the time would be edematous, congested and of a reddish gray tint.

Vomiting is one of the more characteristic symptoms but it is seldom easy to discern whether this is due to trouble in the pancreas or to lesion of the surrounding organs. In a considerable number of instances of chronic dysfunction, from any cause whatever, seen by me the vomiting is of a mild grade, only present at times, and often not much, if any, significance is attached to it. Ill defined and non-ascribable nausea, more prominent even as a symptom than vomiting, deserves mention in this connection.

In the frank cases of chronic pancreatitis no more significant symptom exists than progressive slow loss of weight, especially if this is accompanied with gastric symptoms for which no cause can be gleaned. When in such instances a Cammidge reaction, unabsorbed fecal fat, the Loewi adrenalin mydriasis test, and less than two units exist in the test recently advanced by me (American Medical Association meeting, June, 1924, and to be published in the *Archives of Internal Medicine*) the diagnosis of advanced chronic pancreatitis is warranted.

There is a close connection, as Mayo Robson has shown, between gallstone troubles and interstitial pancreatitis in which the infection of one duct is likely to spread to the other.

Pressure effects (noticed in slow gastric evacuation) in addition to those of the bile ducts may be seen in obstructive symptoms produced by the head of the gland pressing on the duodenum directly or encircling it.

In 1912 Cohn and Pliser called attention to the presence in some cases of pancreatitis of the ocular symptoms associated with excess thyroid activity and reported in five cases that ophthalmos was present in four, VonGraefe's in four, Moebius and Stellwag's in all five and tremor and dermatography in all. If these are present with certain suggestive others they may be of value but in themselves they are not significant.

The clinical test of Loewi's is occasionally of help. This consists of two or three drops of freshly prepared adrenalin solution, one to one thousand dropped into the conjunctival sac and repeated after five minutes. In most all normal people and in many with pancreatic deficiency no dilatation of the pupil occurs in the course of half an hour or an hour. In a few, however, there is conspicuous dilatation, usually excentric in position and often conspicuously oval in form. This test is simple to perform and since it is so often present in exophthalmic goitre (one in three cases) and diabetes (ten out of eighteen cases) it probably is dependent upon irritability of

the sympathetic due to gland imbalance. It has been employed by me often enough in pancreatic disorders of chronic types to make me recommend it as a routine but not to depend upon it alone. It is only a link in the chain of evidence pointing to such a condition and may not be seen in the later stages of the disorder when the play between the two glands ceases to exist.

There now remains the most important of all methods of examination, the indications of abeyance of the external secretion of the pancreas, for upon these alone diagnosis must at most times be based. The pancreas takes a prominent rôle in the digestion of proteins, fats and carbohydrates. When true steatorrhea up to forty or fifty per cent. of dried feces exists, even in the presence of jaundice, it is strongly suggestive of a pancreatic lesion. That steatorrhea may exist as an inborn error of digestion of fats when a full degree of health exists there is no doubt. Garrod reports such a case in a young boy and I have seen three in young adults, the fat percentage being twenty-seven, thirty-six and forty-one and all with normal muscle fibre tests. But what must be remembered here is that fat splitting in digestion may take place normally so far as stool examinations show and still the pancreas may be definitely in dysfunction, and also that there are more factors than lipase in fat digestion. Fatty stools may occur where the alkalinity of the fluids poured into the duodenum are deficient, where there is disturbance of the reversibility action of this enzyme, where resorptive errors exist in the fat lacteals in the villi and where food is hustled too quickly through the small intestine for any cause. While many hold to this test as of negative and positive service, in my hands the factor of error especially in the more moderate grades of dysfunction makes it of questionable clinical value except when there are other distinct symptoms of pancreatic disorder.

Not many worth while observations have been made on proteins. Creatorrhea is of value when marked and there are other symptoms, but there may be no striped muscle fibres present in the stools, the Gross test on casein, the Sahli excretion of iodine or Kashwado's of stained nuclei of calf's thymus may all be negative and yet marked disease may be present. All of these, as well as other messenger tests are of doubtful value especially when in marked disorder of the gland a Kjeldahl estimation may also be negative. When one realizes that trypsin is activated by enterokinase, a secretion of the duodenum, and that there may be a chronic duodenitis in which the enterokinase secretion is deficient although the trypsinogen is abundant, and considers the tryptic properties of the nitrofying bacteria in the intestinal canal it must be evident that no uniform value can come from such tests. This has happened so often in my examinations of cases of definite pancreatic disease that my belief is they are not worthy of continuance.

It may be mentioned here that a procedure that is difficult to perform, time consuming, expensive and possessing the possibility of errors (since all of the physiological matters in the interactions of enzymes are not taken into consideration) such as that of McClure's may be of value in examinations. Where they can be done by competent workers added significance can be gleaned from them.

There now is left the test for carbohydrates or amylopsin, the only enzyme in pancreatic juice that acts directly on starches without assistance from any other agent. For this I would recommend the test recently advanced by me which can be carried out easily and inexpensively as a routine but in the conduction of it I desire to report that after recent studies of the ion concentration best for pancreatic digestion plain water should be employed instead of the suggested buffer solution.

Finally it is my desire to state that there are far more cases of pancreatic dysfunction responsible for digestive symptoms and deficient states of health than has been believed existed heretofore. Some of these are in diabetics in which the islands of Langerhans become finally involved in a chronic pancreatitis. It is my opinion now that loss of weight and strength in diabetes often is due as much to deficiency of external secretion of the pancreas as of internal. All of the instances of gallbladder disease should be carefully examined in pancreatic function and no time should be lost in medical treatment where hypofunction of this gland exists but prompt operation engaged in to eliminate the danger of irreparable harm to the pancreas. Often a gland will work itself up to a higher ability when a diseased gallbladder has been removed. Especially is this true in those instances where at operation a hardened or firmer than normal head of the pancreas is present. When after such operations symptoms of indigestion do not subside or return in a short time and irreparable harm had already been done to the pancreas and postoperative adhesions, return of gallstones, hepatic stones or infections of the hepatic ducts need not be offered as an explanation. Other than the attacks of gallstone colic and jaundice, every symptom of a cholelithiasis case can be and commonly is simulated by chronic pancreatitis alone. If only congestion or low grade infection of the head of the pancreas exists cholecystectomy will restore the function of the pancreas, but once chronic interpancreatitis or intrapancreatitis exists the removal of the gallbladder may do but little good and that's the reason why practically fifty per cent. of the cases of so-called strawberry gallbladders and other forms of low grade infections of the bile sac return with the same spmptoms of indigestion after cholectomy. Another reason is that gallbladders are removed when the symptoms in the first place were pancreatic in origin and the gallbladder figured insignificantly in their production. It should be a routine examination among surgeons to test the pancreatic activity of gallbladder cases before operation, particularly those that are suspected to be without stones, and it would always be wise to remove the gallbladder when the head of the pancreas is firmer than normal irrespective of what the external appearance of the gallbladder is. Only by this routine can a large proportion of these people be saved from intractable and difficult to control digestive symptoms due to hypofunction of the pancreas. The same may be said about the gallbladder in some instances of diabetes, although they are in the minority of all cases; ulcers of stomach and duodenum that are attached to pancreas; and stones in gland ducts.

Lastly, it should be remarked that medical men should consider hypopancreorrhea, regardless of its cause, as a clinical matter, capable of producing digestive symptoms in itself and that these may simulate the symptomatology of most other disorders of the abdomen; and that chronic duodenitis, focal infections and biological errors in the gut can produce dysfunction and disease of this gland. The pancreas is an organ of sequence in the chain of spreading abdominal pathology. It is by no means isolated from effect as its location would suggest, and when affected and in dysfunction unless the cause can be removed and done early enough therapeutically there is little that can be done to relieve the symptoms with the knowledge of therapy we have today.

We have had experience as follows: Several instances of what may be called subacute indigestion, which heretofore were benefitted in any way, that responded magically to pancreas feeding. I believe them to be due to functional depression of the secretion.

Several times in late pulmonary tuberculosis; carcinoma (other than gastric); two instances of pernicious anemia; subacute septicemia; typhoid; combined degeneration of the cord, and in marked debility there has been benefit from suggested therapy—in these I feel that a deficiency of secretion due to adynemia of the gland existed.

Following a sharp attack of biliary colic the soreness in the upper abdomen may exist with anorexia for some days. At this time the pancreatic function is low and is helped by alkalies and pancreatic substance. There may be present then a transient hypopancreorrhea of reflex origin or an acute congestion of the head of the pancreas with low function of the organ.

There were several instances of arteriosclerosis in which, no doubt, the splanchnic vessels were involved causing a low pancreatic ability from deficient blood supply. In these, pancreatic feeding relieved the digestive distress and brought about satisfaction to the patient.

One case of large cyst of the pancreas was followed by digestive distress after operation, a low pancreatic ability was present and the symptoms were relieved by pancreatic feedings of the whole gland, pickled and eaten as a salad each day.

In the primary organic group not much that is encouraging can be stated. A slight degree of symptomatic benefit may come from pancreas therapy and should be tried but when distinct intrapancreatitis or interpancreatitis exists, a marked sclerosis of the head, hemachromatosis, abscess, multiple cysts or hyaline degeneration of the gland but little help is accomplished. Occasionally where diabetes is constant and not controllable, feeding with the pickled whole gland is worth the while.

In the secondary organic group more encouraging results are met with. Of course, where the gland is diseased with carcinoma, syphilis or tuberculosis not much can be expected and the same may be said of sarcoma, late cirrhosis of the liver, Addison's disease, obstruction of the duct of Wirsung or those rare instances of multiple pancreatic calculi. But even here occasionally some symptomatic relief may come. When the gland is in dysfunction in chronic duodenitis, infections of the bile passages and in late achylia cases where a general atrophy of the stomach glandularis exists the relief of symptoms from the gland therapy is often efficient. Here benefit accrues from the taking of an alkaline water followed by pancreatin also in alkaline water before meals, pancreas feeding, or pancreatin with soda bicarbonate, or the least efficient, enteric coated capsules.

On the whole there is no harm in therapy of this sort and it is always worthy of a trial when the test shows the gland's amylopsin units are less than normal.

The Oblique Transrectus Incision for Operations Upon the Gallbladder and Extrahepatic Bile Passages

ABRAHAM O. WILENSKY, M.D.,
New York

The practical characteristics which determine the value of any abdominal incision include, 1, the ease of execution, including the making and closing of the incision; 2, the visibility of the intraabdominal organs, and the ease of intraabdominal manipulation; 3, the possibility of enlargement of the incision when the necessary contingency arises; 4, the possibilities of drainage; and 5, the likelihood of subsequent hernia. In any given case the last two factors are fixed and are independent of any given personality; the status of the first three are always dependent upon the personal equation and characteristics of the operator. These considerations have governed the following remarks as far as possible.

In operating in the right upper quadrant of the abdominal cavity, many surgeons have become dissatisfied with the usually made vertical rectus incision, especially when operating upon the extrahepatic portion of the biliary system—the gallbladder, the cystic, hepatic and common ducts. The difficulties usually encountered are said to include insufficient exposure, difficulty or impossibility of properly closing the incision, and the tendency of all vertical incisions to gape under strain, thus forming, perhaps, a predisposition to the subsequent appearance of hernia in the scar.

Other types of incision have, therefore, been proposed and practised, all of which attempt to obviate the disadvantages of the vertical type. The incisions proposed as a substitute for the vertical one generally conform to one of several types: 1. The vertical line is abandoned altogether and the line of direction of the incision is transverse (Duncan, Morison, Sprengle). 2. A transverse incision is

combined with a vertical one (Perthes, Czerny, Koenig-Kehr). 3. An oblique incision is made directly through the abdominal wall (Curvoisier, Kocher, Kohrte). 4. A vertical incision is combined with an oblique one (Mayo Robson).

More recently in this country attention has been called to the transverse incision by Farr, by Moschcowitz, and by Meyer. It has been recognized that an incision made in the transverse direction loses the tendency to gape during strain and closes more tightly together. Importance is laid upon the unexcelled visibility of the abdominal viscera through this incision and upon the ease of closure. In the earlier reports it was affirmed that a reopening of the wound hardly ever occurred, even if it became infected; and that necrosis of the fascia was practically never seen even in the presence of infection; subsequent hernia did not occur in the first groups of reported cases. Drainage is possible at any point.

The disadvantages of the transverse incision are: 1, the excessive length of time consumed in making and suturing the incision; 2, the impossibility of easily and properly rotating the liver out of the belly; 3, the occasional insufficient exposure; and 4, the difficulties encountered in attempting to reach other viscera (organs in the lower half of the abdominal cavity—appendix, caput coli, etc.) The only method of enlarging the transverse incision adequately, when such contingency arises, is to add a vertical limb to the transverse incision; the former can be directed either upwards (the Koenig-Kehr method) or downwards. If for one or another reason the addition is not possible or advisable, the only thing left to do is to close the original incision altogether and start anew.

I have never been attracted to the transverse incision and I have personally never made use of it. I have seen accidents happen in transversely made incisions, as well as in others. I have seen the wound break open in the absence of infections. There are also by now instances in which herniæ have subsequently appeared. One of the reasons for these accidents lies in the character of the incision in which the various layers of the abdominal wall are divided in one plane. This would make a fault in any kind of an incision. There is also no opportunity for any overlapping of the various layers, or no possibility for one layer of the abdominal wall—the muscle—to protect the suture line in the other layers by overlying them. Such advantage is only secured by altering the plane of incision in each of the layers of the abdominal wall. If for any reason—the poor condition of the patient, for instance—union between the cut surfaces is not immediate and firm, the absorption or weakening of the absorbable sutures customarily used makes for ideal conditions in which the slightest strain on the part of the individual causes the wound surfaces to part—this in spite of the tendency all transverse incisions have of closing more tightly together during exertion.

Another important factor in transverse incisions is the length of time necessary for their proper making and, especially, for their proper closure. If one does not possess the gift of rapid operating, this may equal almost or exceed the time necessary for the entire intraabdominal manipulation. Rapidity of operating is of maximum importance in my patient not in the best of condition and of great value in any other patient; modern surgery has taught everyone that the ability to "go in and get out" quickly in abdominal operations with the maximum speed consistent with thorough and efficient work is directly proportional to the comfort, absence of complications, rapidity of healing and shortness of the postoperative convalescence. With a slow operator, the time consumed in closing a transverse incision, if carefully done, can become interminable.

I have, however, seen a number of cases in which the transverse abdominal incision has seemed to have an especial indication. I refer to the cases in which at previous times it had been found necessary to operate repeatedly in the upper abdomen, so that at the time of presentation the upper abdomen bears three or four vertical scars. Each of these necessarily bears its full quota of intraabdominal adhesions, oftentimes made more complicated by the fusion of the one with any or all of the others. If laparotomy is again indicated, it has seemed to me that a transversely placed incision would give access to all of the adhesions resulting from the previous operations, would enable a more rapid, less difficult and less dangerous separation of them, and a more adequate exposure of the operative field, and would relieve the operator from the impediment of adhesions which he could not reach through any single vertical incision. In one particular case which I have in mind the transverse incision proved an excellent one, and accomplished everything that was hoped for.

The combination of a transverse and a vertical incision, the rectangular incision, is the type characteristic of the older surgery—that done twenty or more years ago—and of the German school. The first of these was proposed and practised by Koenig and Kehr. It consists in making an incision through all the layers of the abdominal wall from the xiphoid along or through the inner border of the rectus muscle and then extending it at right angles to about the anterior axillary line. The line of incision extends in the same plane through the layers of the abdominal wall. Before dividing the rectus muscle, it is stitched to the fascia as in the ordinary transverse incision. The access obtained and the visibility is superb. Drains may emerge at any point of the incision.

The second variety is the Perthes incision, in which a rectangular skin muscle flap is raised. All the structures down to the posterior rectus sheath are incised as in the Koenig-Kehr incision; the muscle is also stitched to the anterior rectus sheath. The whole mass is reflected backward as far as the costal margin. The posterior rectus sheath and the peritoneum are incised in an oblique line parallel to the costal margin and about one third of an inch in front of the point of emergence of the last two intercostal nerves.

In America, Willy Meyer has, apparently, had most experience with this general type of incision. The superior advantages of the Perthes incision is said to include: 1, an exceptionally wide access; 2, preservation of the nerve supply; 3, the difference in plane of incision between the skin muscle flap and the posterior rectus sheath and peritoneum; 4, the possibility of rotating the liver out of the belly; 5, less packing is required; 6, drainage can be carried

out at either end of the incision and not at the centre.

In cases of necessity it is a most difficult matter properly to enlarge the Perthes type of incision without undue mutilation of the muscular tissues of the abdominal wall. The Kohrte-Kehr type of rectangular incision is superior from this point of view, although the mutilation of tissue is also unduly excessive; the incision can be enlarged at either of its ends; the transverse limb may be continued across

Fig. 1. Fig. 2. Fig. 3.

Fig. 1.—Projection surface anatomy of the organs in the right hypochondrium. The heavy dotted line indicates the margin of the rectus sheath. The oblique heavy solid line shows the line of incision through the skin and the anterior sheath of the rectus muscle. The centre of the incision overlies the junction of the common and hepatic ducts.

Fig. 2.—The drawing shows the anterior rectus sheath. The heavy solid line represents the line of incision through the anterior rectus sheath and shows the relation of the incision to the costal margin and to the outer and inner margins of the rectus sheath.

Fig. 3.—The drawing shows the interior of the rectus sheath after the anterior sheath has been cut away and the rectus muscle has been removed. The cut surfaces of the muscle are shown at the upper and lower limits of the sheath. The costal arch is shown at the upper left hand corner. The floor is the posterior rectus sheath and the heavy solid line shows the line of incision through it. In actual practice the rectus muscle would have been separated in the course of its fibres and retracted laterally.

the abdominal wall to the opposite side; or the vertical portion may be continued downwards below the level of the transverse. All such manipulations, however, consume an excessive amount of time which could be more profitably employed.

If the vertical limb is made to run through the linea alba it becomes a source of weakness. The junction of the two lines of incision is a point of special weakness. In either case the potentialities for a postoperative hernia are at their maximum.

The disadvantage of the rectangular type of incision—the combination of a vertical and transverse incision—represents exaggerations of those characteristic of the transverse incision alone and are added to by those of rectical incision. The time consumed in making and, especially, in closing such a wound is out of all proportion to that required for the intra-abdominal manipulation. When the whole thickness of the flap is considered it is seen to form more or less of an impediment because of its very bulk, and in stout subjects the impediment becomes considerable. Apparently, whatever is gained in visibility and in increased accessibility is more than lost in one of several other directions. The fact that this type of incision is so seldom employed in American circles points rather forcibly to the fact that in this country, at least, the disadvantages are considered far to outweigh the advantages.

An oblique incision was proposed by Curvoisier and practised also by Kocher and Kohrte. This practically follows the oblique direction of the posterior rectus-sheath-peritoneum portion of the Perthes incision; the line of incision extends, however, through the entire thickness of the abdominal wall in the same plane. Visibility and accessibility are good with this type of incision and the liver can be rotated out of the abdominal cavity. The possibilities of extending the incision in case of necessity are practically of the maximum degree; but any enlargement is made at the expense of mutilation of the broad muscles of the abdominal wall which, at least to my ways of thinking, is entirely unnecessary and unjustified. Drainage can, of course, be carried out at any point of the incision.

The disadvantages of the oblique incision are practically the same as those of the transverse incision.

In operations in the upper abdomen, Arce, of Buenos Ayres, uses the following incision: A transverse skin incision is made from a point two fingers breadth outside of the median line to the axillary line, a little beneath the costal margin and running approximately two inches above the umbilicus. When the skin and cellular tissues are divided the fibres of the external oblique muscle are separated widely as the wound will allow and down to the external edge of the sheath of the rectus muscle. The fibres of the internal oblique muscle, seen running through the lower border of the wound aperture, are also similarly separated in all of their visible extent. The anterior part of the rectus sheath is divided transversely and the rectus muscle is retracted inwards. The transverse abdominal muscle and the posterior rectus sheath and peritoneum are then sectioned transversely.

This is practically a McBurney incision in the upper abdomen combined with the Weir modification. Free use of drainage would be difficult except at a point outside of the rectus sheath. The suture of the wound would occupy much time, if properly done. If such a wound ever became infected, the resulting suppuration would be widely spread, would occupy practically every layer of the abdominal wall inside and outside of the rectus sheath, would be accompanied with much fascial sloughing, and the potentialities for a subsequent hernia would be of maximum degree. The hernia would be a large one and its repair would be difficult. I do not know of anyone who has had experience with this incision when made in the upper abdomen except Arce. Personally, I cannot see its value. The very fact that Arce must make free and liberal use of retraction indicates that the resulting net opening does not always satisfy him and would not satisfy most operators; that there is more or less cramping. Nevertheless, Arce has done twenty-four laparotomies with this incision and is very satisfied with it.

Taken all in all, it seems fair to say that the type of incision in which a vertical limb is combined with a transverse or oblique limb has not completely filled the bill. The simple oblique type of incision—Curvoisier—has also been unsatisfactory.

For the last ten years I have been making use of an incision for operations upon the gallbladder and bile ducts which I believe combines the best qualities of all of the various incisions described above. I make it as follows:

An oblique incision is made beginning practically at the median line and high up near the ensiform and proceeding downward and outward to the outer border of the rectus sheath. The obliquity of the incision depends a great deal upon the amount of adipose tissue present, and upon whether the subject is of the long, thin type or of the short, thickset type.

The point where the incision begins depends also upon the character and size of any mass which may be present, but as a general rule, I begin the incision about one inch below the ensiform process. This incision divides the skin, the subcutaneous tissue and the anterior sheath of the rectus muscle in the same plane. The fibres of the rectus muscle are bluntly separated and retracted. The plane of this division is usually at about the centre of the muscle. Sometimes, when the gallbladder lies rather far out, the muscle fibres are separated near the outer border of the muscle; very seldom is it necessary to make the division closer to the median line. The muscle is usually of sufficient pliability to stretch easily under retraction so that the entire length of the incision is exposed. If any fibrous intersection intervenes, the intersection is first dissected free from the overlying sheath of the muscle, before the muscle fibres are bluntly separated. Too vigorous retraction in the hands of an inexperienced assistant sometimes results in tearing the muscle, but this can and should be avoided.

The posterior rectus sheath and the peritoneum are divided in the same plane, or a little to one side of the plane of the superficial part of the incision going through the skin, subcutaneous tissue and anterior rectus sheath. The course of the incision, however, corresponds exactly in its obliquity to the latter. This results in an oblique incision in which all layers of the abdominal wall with the exception of the rectus muscle are divided in an oblique direction, in which the rectus muscle is not divided across its fibres, but only bluntly separated and in which the entire incision lies within the confines of the rectus sheath.

By altering the obliquity the incision can be made as large or as small as one wishes, or expects to need for the adequate accomplishment of the intraabdominal manipulations. The average operator can almost always know in advance just how large an incision will be necessary and the incision can be planned accordingly. The possibilities for drainage are as good as in any other similar incision of the best type. The incision can be rapidly made and just as rapidly closed. When well made this incision gives the most adequate exposure at the point most needed—just at the neck of the gallbladder and the junction of the cystic, hepatic, and common ducts. This point, the centre of the entire operative attack, lies directly under the centre of the incision. The liver can be easily rotated out of the abdomen and visibility and ease of access are the par of any, and superior to many of the other types of incisions previously described; in a thin subject these are superb.

This incision avoids all the disadvantages characteristic of the transverse or oblique incisions, or of combinations of these with the vertical incision in or near the midline. There is no division of any muscle fibres, either in the rectus muscle or in the broad muscles of the abdominal wall. The nerves are not divided at any point. The various layers of the abdominal wall are divided in various planes; the suture of the one protects the other; and the intact rectus muscle guards the whole.

The incision contains all the best qualities of the transverse (Duncan, Morison, Sprengle) and of the oblique (Curvoisier) incisions. There is approximately the same ease of exposure and the same visibility. The line of incision approaches the lines in which strain of any kind approximates and does not distract the lines of incision. In suturing the wound, the difficulty in approximating the peritoneum, usually encountered in vertical rectus splitting incision, is absent and the suture can be done with ease.

There is no difficulty in reaching, exploring and operating upon other organs in the vicinity of the upper right quadrant. I have sewed up perforated ulcers in the duodenum or stomach. I have done pylorectomy. Many times it has been easily feasible to reach down and remove the appendix without enlarging the incision. One time I did a nephrectomy when I accidentally found a hypernephroma. In isolated instances in which it was found necessary to enlarge the incision, it was possible to do so with the greatest of ease and with the loss of only a few seconds of time. This was done by continuing the incision downward as a vertical prolongation of the oblique; all of this was done within the rectus sheath and did not materially alter the primary incision.

One can see that this incision has the best qualities of the vertical types of incisions practised; of the muscle splitting, or Kammerer type of incision. Easily these, as a general class, are the superior of any type of incision made. They are easy to make and just as easy to sew up. They take the least time. They heal easily, quickly, and efficiently. They give the best access and the most visibility. They are easy to enlarge and the enlargement can reach any proportion desired. One can reach equally well above and below and to the left side almost as well, as quickly, and as easily as in the right. Infection in the line of incision does not spread within the layers of the broad muscles of the abdominal wall, is rapidly localized and controlled, is easily dealt with, and heals most quickly.

It has always appeared to me that while one ought not to bind oneself absolutely to any one incision and that one should, as far as possible, have an equal facility with all types of incision, for ordinary work and for the average surgeon, it is much the better plan to school oneself in one type of incision and to make use of that as far and as often as possible. With added and repeated practice the incision becomes better and better, easier and easier, more and more adapted to all of the given purposes. One learns to handle such an incision to the greatest advantage and things that are at first difficult later become of no difficulty at all. The search after new incisions, the transverse or other, sometimes defeats its own purpose.

Historical Medicine

The Note Book of a Guy's Hospital Student

G. ARBOUR STEPHENS
Swansea, Wales

Recently I have become the possessor of an interleaved book entitled "A Syllabus of the Lectures on Midwifery Delivered at Guy's Hospital and at Dr. Lowder's and Dr. Haighton's Theatre, in St. Savior's Churchyard, Southwark." The book was reprinted in London in 1799, and the interleaves fully written up by Thomas Gething Williams, who practised the art of medicine for many years in Swansea.

There is one interesting note on the *Diseases of Infants Requiring Medical Treatment,* of which Williams has written: "It must be evident that it is a difficult part of Medicine, consequently Practitioners do not much like it, the causes of complaints not being at all evident, not being able to get any information respecting them as an adult can give you, it is common to ask the nurse questions. They often form opinions of their own of the causes, & would mislead you, therefore do not suffer your judgement to be misled by them, only ask questions of the feeding of child." "A set of questions laid down which are to be asked in all cases, which are respecting the actions of child, whether it draws its knees up, which is a sign of Gripes; if it puts its fingers to its Gums & pull them about, a sign of teething; if it picks its nose, a sign of irritation of the Intestines, as worms; fretful & puts the hand often to the head and shifts it about often it may be hydrocephalus"

The punctuation can hardly be said to be first class, while the simplicity of the diagnosis is such as to appeal to the most tired student in the university.

With regard to Cæsarean section he writes: "It is impossible to say how many would recover from it out of a number but the probability is from the injury necessarily done in the performing of it that but one out of a number would be saved. Many have thought that the admission of air into the cavity of the abdomen did the most injury, & was the principal cause of death in those cases, but Dr. Haighton does not think so & has proved by experiments in animals that air does not do the mischief, but that it is the injury done to the parts otherwise is the cause of death."

If Dr. Haighton had but carried on with his vivisection experiments, it is quite possible that Guy's might have been in the position to claim the honor of having enunciated the germ theory, though on second thoughts I think that even with that 'if,' the credit belongs to an Englishman named E. Maynwaringe, Doctor in Physick, who published a book in 1673 on *The History & Mystery of the Venereal Lues or French Disease.* He tells us in this book, "To the act of infection there are three *requisites,* the person or body *infecting* that does communicate; secondly the virulent Miasm transmitted or communicated; thirdly the person infected." "In the next place we are to consider what these *miasms* or infectious seminaries are that pass from body to body. Some call them *vapour,* others a *spirit,* but we shall not trouble ourselves upon the name, provided we rightly know what is meant thereby." "We are therefore to understand them as corpuscles or subtile finer invisible bodies, which are minute small portions, exhaling from infected bodies of the same nature & taint as the bodies from whence they were emitted. These venenous *particles* of contagious matter are agile and penetrative, that they insinuate themselves through the pores of other bodies; and being entered do then ferment and operate to alter, & change their new *receptacles,* and *tincture* them with the like *labes* of their own virulent nature."

Is Maynwaringe an old Guy's student? If so, the hospital can still lay claim to one who, in the words quoted above, has been undoubtedly the first to enunciate in unmistakable terms the fundamental idea underlying the modern germ theory. In 1672 or over two hundred and fifty years ago, just after the Commonwealth had become a matter of past history, this unrecognized genius enunciated the theory which in the hands of Lister and his pupils has changed the whole outlook of surgery as well as of medicine.

Hear what Maynwaringe has to say of phthisis: "and as for a phthisis, why that should be infectious to the lungs of another, there is good reason for it; because the *corrupt* breath going out of the *phthisical* person is drawn in & received by another, and having imbibed *phthisical* corruptive *miasms* in the breath, may lodge & fix there, changing the natural *tone* of the lungs into a *tabid* & corruptive state."

Turning back to Gething William's notebook, one finds a few words on lues venerea in infants, and it is interesting to note that Dr. Haighton uses the same nomenclature as Maynwaringe—the venereal lues. "The 3d Division is those diseases that make their appearance after Birth as Venereal Disease. A case of this kind would be more equivocal in an Infant than in adults, as they inform you of circumstances by which you could decide that it was such in children you are not to expect sores on the genitals more than any other part, they receive it from the mother, therefore it is in her proved to throw some light on it. They will be candid sometimes & say they have been injured by their husband."

One cannot but feel that the information communicated to Gething Williams as evidenced by his notes is very important (although he writes fully), and compared with the very full information which we get from Maynwaringe in 1673, it is very unsatisfactory. Maynwaringe points out how syphilis in infants is either "*hereditary* or adventitious," but to a student like Williams no such instruction seems to have been given.

Williams tells us that "Dr. Haighton recommends all to be backward in recommending wet nurses as they are always more troublesome than other servants, give themselves airs, etc., & their characters may be bad as to the health of the woman & the goodness of milk, can't say that will be proved from the effects on a child. Should never recommend any so as to be at all responsible for them—might be diseased. An instance of Dr. Orm getting into a scrape by recommending a Nurse who had the venereal disease. She gave it to the footman, & he to the Housemaid. The master was likewise fond of the Nurse. She gave him the venereal disease, & he gave it to his wife the mistress."

With this tale the notes end but on the last page are printed the Regulations for midwifery students on the District.

1. Each gentleman will have labors in proportion to the number of courses he subscribes to, and will be served in rotation as nearly as the nature of things will allow.

2. Before any gentleman is called upon to act he will have an opportunity of attending the lying in house, where he will have the means of acquiring the necessary preparatory knowledge.

3. No gentleman who has been called upon to attend a labor either at the lying-in-house, or at a private house, can be permitted to take with him another who has *not* been called to it; nor can he send another in his stead.

4. Notice to be in readiness to attend a labor will (when time will allow) be given to each gentleman, either by verbal message or in writing; & it is recommended to him to accept of the offer if possible; in any case a decided answer is expected.

5. Every gentleman engaging to attend a labor when called on, will (agreeably to his own promise) be expected to hold himself in readiness for that purpose; but in case of failure, & it becomes necessary to send another in his stead (a circumstance that must always be attended with vast delay & much inconvenience, & often danger to the patient) the gentleman committing such neglect forfeits one labor from the number allotted to him.

6. Every gentleman who goes to a labor is expected to stay until it is finished but in case he is called where the patient is under a mistake, he may leave her, having personally taken proper methods to acquire the necessary information. In this case it is recommended to him to call on her again soon, & in case of disease Dr. Haighton should be informed of it.

7. In case of difficulty or danger during labor, the gentleman attending is requested to send, if possible, a written message to Dr. Haighton; but he is on no accord to leave the patient.

8. It is recommended to each gentleman going to a labor to have with him an opiate, and some common aperient medicine, such being frequently wanted after delivery.

9. As every gentleman undertaking a labor necessarily pledges himself to attend the woman during her recovery, he will consequently see the propriety of calling on her each day until she is in a perfectly safe condition, & in cases of serious indisposition Dr. Haighton should be informed of it.

Contributors to the Science of Medicine

Pierre and Marie Curie

It would be impossible to write a sketch of the life and work of one of the Curies without including an equal amount of material about the other. So closely allied were they in their lives, work, thought, and ideals, that even now, when Pierre Curie is no longer here to carry on his great service to science and to mankind, his wife lives only to perpetuate their common work and aims.

Pierre Curie's parents were intelligent, educated members of the bourgeoisie, with small means. His father and grandfather were physicians. The family was of Alsatian and Protestant origin. Dr. Eugène Curie, Pierre's father, received his scientific and medical education in Paris. He was a man of unusual charm and handsome appearance, and of brilliant mentality. He had wished to consecrate his life to science, but the responsibilities of family life had made it necessary for him to practice medicine instead. Throughout his life, however, he continued to make as many scientific investigations as possible, especially in the natural sciences. He loved the country, with its plants and animals, and this love and interest were shared by Pierre, who always found adjustment to city life difficult. Although Eugène Curie's medical career was a modest one, it showed nevertheless unusual qualities of devotion and disinterestedness. During the Revolution of 1848 the French government conferred a medal upon him "for honorable and courageous conduct" in treating the wounded. During the subsequent epidemic of cholera, he installed himself in a quarter of Paris that had been deserted by physicians, in order to care for the sick. During the Commune he established a hospital in his apartment and cared for the wounded there. He was a freethinker and an anticlerical, did not have his children baptized, nor encouraged them to follow any form of religious exercise in their family life. Their mother, Claire Depouilly, came of a rich manufacturer's family, who, however, lost all their wealth because of the Revolution. These losses and the reverses suffered also by Eugène Curie in his medical practice from the same cause were bravely and even gaily borne by the young wife and mother. These traits and qualities of the parents, and the general atmosphere of refinement and culture, high ideals,

modest living, and gentleness and affection in family life, were reflected in the lives and characters of the two sons, Jacques and Pierre.

Pierre was born on May 15, 1859. He was three and a half years younger than his brother Jacques. The two brothers were devoted and whenever possible in the closest contact throughout their lives. They were very different in temperament and personality, but this seemed to increase their affection and congeniality. One of the little Pierre's earliest memories was of a battle near their house in Paris during the Commune, of the hospital established by his father there, and of the expeditions made by him and Jacques to search for the wounded.

PIERRE CURIE

MARIE CURIE

Pierre never went to school in his boyhood. His mother taught him at home, then his father and his older brother, whose attendance at school had also been very limited.

Pierre would accompany his father on country rambles when they lived at Sceaux, and the two would never tire of observing and studying the plants, birds, and animals which they found along the way. The father's natural taste for literature and his excellent library were the sources of Pierre's early education along these lines. When he was fourteen, he became a pupil of Professor Bazille, who taught him Latin, in which he was sadly remiss, and mathematics, for which he had a remarkable aptitude. Thus began the training which was back of so much of Curie's later work with physical laws and phenomena. Thanks to his rapid progress in mathematics, he became a bachelor of science at sixteen. Soon after he began to prepare for his licentiate in physics, taking courses at the Sorbonne, working in the laboratory of the School of Pharmacy, and with his brother in his chemistry courses. He received his licentiate in the physical sciences when he was eighteen years of age, and at nineteen was appointed preparator for Desains in the physical laboratory of the University of Paris. It was here that he began his experimental research.

Madame Curie describes him at this time as a tall, slender young man with chestnut hair and a shy and reserved expression, but with a profound inner life mirrored in his youthful face. His vacations were always spent in the country with his brother. The two would take long tramps, sometimes lasting for days at a time, interspersed by swimming, diving and other outdoor sports. They would then return, happy and refreshed, to their laboratories in Paris, ready for their investigations. Their first great success was the discovery of the hitherto unknown phenomena of piezoelectricity, or polarization produced by the compression or expansion of crystals in the direction of the axis of symmetry. The piezoelectric property of quartz has recently been utilized in the production of elastic waves of high frequency sent out in water to detect submarine obstacles. In 1883 Pierre was made director of laboratory work in the School of Industrial Physics and Chemistry of Paris, where he later became professor. He spent twenty-two years of his life in these old buildings of the College Rollin, where he was greatly loved and admired by all who came near enough to him to break through his temperamental reserve and shyness. The whole period of his scientific career is marked chiefly by desperate struggles to achieve results with limited and poor equipment, lack of funds, a bare livelihood for his personal necessities, and for the most part lack of appreciation by the scientific world, perhaps caused or at least augmented by his positive refusal to advertise either his work or himself; to ask for any advances, either of pay or position; to accept any honors; or even to appear in public except when it became absolutely necessary. He had reached the age of thirty-five before he decided to present his doctor's thesis—the results of his work on magnetism.

In 1894, Pierre Curie met Marie Sklodowska, of Warsaw, the daughter of Catholic Polish parents, both of whom were teachers in the elementary schools of Warsaw. At this time she was in Paris fulfilling a long cherished dream of studying science in the French capital. They became friends at once through the discussion of scientific and sociological subjects, and it was not long before Pierre realized that this serious, intelligent Polish girl was, as he would often tell her later, the "wife made expressly for him to share all his preoccupations." Yet he was able to write to her before they were married: "We have promised each other (is it not true?) to have, the one for the other, at least a great affection. Provided that you do not change your mind! For there are no promises that hold; these are things that do not admit of compulsion."

He was married at the age of thirty-six, an advanced age in France for matrimony. He had believed that it would never be possible for him to find a wife who could live his dream with him. That he did so has been amply proved. His unshakable faith in science, and in its power to further the good of humanity remained throughout his life. Like Pasteur, he "believed invincibly that science and peace will triumph over ignorance and war."

The first home of the young couple was a very simple one, consisting of a little three room apartment whose chief attraction was a view of a large and beautiful garden. Madame Curie did all the house work, ordering it so as to interrupt as little as possible the scientific researches which she was permitted to carry on with her husband in his laboratory. They spent their short vacations walking or bicycling in the country near Paris, until the arrival of their baby Irene. Shortly after this event Pierre's mother died, and Dr. Curie came to live with the young couple, thus helping to solve happily the problem of someone to help care for the baby while the mother was busy in the laboratory.

Marie Curie's attention had been already caught by Henri Becquerel's accidental discovery of the spontaneous emission by uranium salts of peculiar rays. Also Röntgen's recent discovery of x rays was then arousing much interest and exciting the imagination. Experiments along this line led to peculiar phenomena of so interesting and unusual a character that Pierre Curie abandoned his work on crystals to join his wife in her investigations. The detailed and complicated steps leading to the discovery in 1898 of the existence of polonium, and, a few months subsequently, of radium, after an all night vigil in the laboratory, are too involved and technical for repetition here. The remarkable thing is to remember that for two whole years these investigations, which led finally to the reduction to nothing of the theory of the absolute fixity of the whole atomic edifice of science, were made in a wooden shed with a glass roof, far from rainproof; with no heat but a stove which barely warmed its immediate vicinity; and with no means of getting rid of the poisonous gases thrown off by the chemical treatments, so that when weather permitted these processes had to be conducted out in the court. Dust and dirt interfered with results, and there was no equipment but a few rough, worn pine tables, and a blackboard. At first the work was financed from the meagre resources of the Curies themselves; later a few donations were received. No assistant could be afforded, so often Madame Curie would pass most of the night stirring the compounds in their great containers with an iron bar almost as big as herself. Their greatest joy was to return to their rude shed in the evening and survey their domain in the darkness, their precious, unprotected products on the tables and shelves against the walls, gleaming faintly like souls being born out of the void.

Finally appreciation, fame and many honors, few of which were publicly accepted, came to the Curies, and in the end more ample remuneration so that life was made comfortable, at least, and assistance and equipment for their work became feasible. A second daughter was born, and the little family, still including Dr. Curie, passed a happy time in the little house in the Boulevard Kellermann. Pierre Curie in 1904 was named titular professor of the Faculty of Sciences of Paris. Just as prosperity and ease were becoming actual facts, came the brutal accident which snuffed out a life that had meant already more than is yet known to science and human welfare, and was destined to mean infinitely more. Pierre Curie, leaving a reunion of the Professors of the Faculties, was crossing the street when he was struck by a motor truck and instantly killed. His wife writes: "So perished the hope founded on the wonderful being who thus ceased to be. In the study room to which he was never to return, the water buttercups he had brought from the country were still fresh."

It is of some consolation to know that, in the carrying on of the work undertaken with her husband, Madame Curie has at last been provided by various individuals, institutions and organizations with the means to do it in the proper manner and under favorable conditions. The story of the presentation to her of a gramme of radium by the women of America, and of her visit to this country a few years ago to receive it, is well known. Perhaps the most characteristic incident of that visit was Madame Curie's refusal to accept the radium, even for one night—"I might die," she said—in her own name, and her insistence that a new "deed" be drawn up at once, making it the property of the Institut du Radium of Paris. She, like her husband, believes, and lives up to the belief, that "in science we should be interested in things, not persons."

Under the Red Light

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland

"Then take scarlet cloth and completely envelope the smallpox patient therein. I followed this practice in the case of the grandson of the very noble King of England, who suffered from this malady. I insisted firmly that everything surrounding the (patient's) bed should be red and thus I cured him without any remaining trace of his variola." This sentence translated from John of Gaddesden's *Rosa Anglica*, the first edition of which was published in 1492, is the first printed mention made of an original means of treating the eruptive fevers. Whether or not this treatment was known before the time of Gaddesden, who lived between 1280 (?) to 1361, is difficult to state with certainty, but it is infinitely probable that it was, regardless of the fact that it is not referred to by any of the Greek or Latin writ-

ers, with the exception of a verse of Propertius which is far from being convincing. But China and Japan knew it from time immemorial, and it is a curious fact that this practice is still greatly in vogue in various parts of the world, in Caucasus as in the Voges and Poitou, at Tonkin as in Roumania. The fact that this treatment is so universally known might seem a proof of its antiquity.

From Gaddesden's day we meet—as we descend the course of the centuries—this therapeutic measure referred to by numerous writers—thus in 1537 by Astiarius, Simon de Vallembert in 1565, a little later by Mercurialis, and after him, by Ambroise Paré; G. Blaise in 1656, Eloy in 1744, Rosen de Rosenstein in 1778. Then came the nineteenth century, during which this therapeutic measure fell into disrepute, until the day came when Finsen, in 1893, took it up again and developed the indications for erythrotherapy.

At the Folk-Lore Museum at Antwerp is exhibited a red silk scarf, which was used to treat sore throat, a custom which still is in vogue among the peasants of Poitou.

The ancient Chinese physicians applied a swab of cotton impregnated with carthamin and soaked in a solution of red pigamon which was applied over the region where the first pustules of smallpox appeared. Recently, this direct treatment has been resorted to by means of fuchsin and scarlet red. There is a race in Australia who swab the face of a patient ill with measles with dog's blood. More frequently, however, red clothing is used, and King Charles V was dressed in red shirt, stockings, and veils, when stricken with smallpox.

Quest of the Unicorn in Fact and Fable

The announcement that MacMillan has brought back from the Arctic seas a tusk of the narwhal, one of the least known of all mammals, brings to mind a curious superstition which began with the ancient Greeks and which may not be quite dead today, writes Odell Shepard (*New York Times Magazine,* October 19, 1924). From the fourteenth to the seventeenth centuries, Scandinavian sea rovers scoured the north Atlantic in open boats, looking for narwhal tusks, which they sold to kings and princes of Europe for fabulous prices. No banquet table was thought complete or even safe without one. Those who could not afford an entire horn were glad to get small pieces, which they had carved into drinking cups or set into the handles of their table knives. For these overgrown teeth of a small sea mammal were thought to be the horn of the magical unicorn of fable, which, according to the best authorities of the Middle Ages, had the interesting and valuable habit of breaking into a profuse and visible perspiration whenever poison of any kind was brought into its presence. "It was this habit which attracted the attention and won the enthusiastic approval of the crowned heads of Europe, and particularly of the Italian tyrants. Every one of these men felt that he must own a horn in order that he might sit down to a dinner without feeling that he might never arise, without suspecting every dish set before him. . . . . Everyone except the professional poisoners believed in the horn's efficacy, and continued to do so until the classic age of poisoning had gone by." Among other devices used at this time for detecting poisons were snakes' tongues suspended above dinner tables on gilded tongue stands; the supposed horns of the cerastes, a fabulous Egyptian serpent, were similarly treated. In less wealthy establishments, the vulture's foot was hung over the flame of a candle in the belief that when poison was brought upon the table it would extinguish the flame.

So far as is recorded, the earliest authority to write about the unicorn was Ctesias, a Greek physician at the Persian court, who lived in the fifth century B. C. and wrote a book about India. In this book he describes the unicorn as having a white body, a red head, and blue eyes. "Each has a horn the base of which is white, the end red, and the middle black. Drinking cups are made of these horns, and those who drink out of them are said to be subject neither to spasms nor to epilepsy, nor to the effects of poison." Aristotle, Aelian and Pliny all repeat this description, except the color scheme. The Christian symbolism in which the unicorn represents Christ is well known. "Belief in the unicorn and in its miraculous powers thus became almost an article of religion. The animal became almost sacred so that any man who doubted that its horn could detect poison would probably have been rated as an infidel. Even the most critical went no further than to propose a series of tests whereby the true horn could be known from the false. The real horn was said to produce bubbles when thrown into water, to purify poisoned wine, and to perspire in the presence of poison."

The unicorn superstition flourished until about the middle of the seventeenth century, when the scholar Kirschmayer saw a narwhal sporting the supposed horn of the unicorn. He communicated his doubts, and suspicion increased until the Great Sophy sent a horn to Charles II, who turned it over to the recently founded Royal Society of London to experiment on. The investigators surrounded the horn with all the deadliest poisons known, but nothing at all happened. Yet for a long time the delusion was cherished, even Sir Thomas Browne in his *Vulgar Errors* treating the animal very cautiously; but his son, Dr. Edward Browne, was quite disillusioned, speaking of unicorn horns in 1685 as a drug on the market. Nevertheless powdered unicorn horn was still in request for more than a hundred years after the Royal Society's experiment, and was kept on the official pharmacopœia of London until 1742. In the royal court of France a horn was used for testing the King's food until the Revolution of 1879 devised a better way of getting rid of kings. In Hogarth's painting, Marriage à la Mode, a narwhal tusk may be seen hanging on the wall of the quack doctor's shop.

Editorial Articles

HERE AND HEREAFTER

It is not an ordinary occurrence that can turn the stomach of a physician, but we have to confess to a sense of nausea in looking over a parliamentary report by Sir Edwin Chadwick (the "father of public health in England") on *The Practice of Interment in Towns* published so recently as 1843.

It was not so much the account of the practice of interment as of lack of interment, or delay in interment, that produced the effects. This delay often extended, among the poor, to a week or even two weeks, sometimes from disinclination to part with the body of the deceased but more frequently from inability to collect the funds for the burial, or rather for the social observance accompanying the burial. Meanwhile holes had often to be made in the coffin to drain off the products of decomposition, for there was no such thing as embalming in those days, and not infrequently these juices poured down the shoulders of the bearers—but we would not communicate our stomachic disturbance to the reader, so we forbear further details.

It is good, however, to know that even as regards funerals the world does progress—and as for the living, we doubt whether in England it is now often the case that there are to be found a dozen people living in one room. No wonder that funerals were an expense, for they came so frequently, especially among children, even when they were not in themselves costly.

When we read of one grave being made large enough to hold fifteen hundred persons we can appreciate the horrors of epidemics of the day. No wonder that cemeteries were often a real public nuisance and that it was believed they were a menace to the health of those in the neighborhood. In fact they were more of a menace than we can now appreciate.

Death has a terrible sting and the grave still seems mightily victorious, but a philosophy, less materialistic than we have known, is finding its way into the general consciousness as our ideas of matter and of mind broaden and interlace. After all, we know as much about the future as we do about the past —about the whither as the whence, and the latter deserves as much of confident hope as the other our wonder and respect. No less a light in science than Verworn believed in cell consciousness as well as in the consciousness of organized collection of cells, and who knows but, as Samuel Butler ingeniously suggested, the launching of the ovum on its way to be a human being may be looked upon by it with as much foreboding as the finished (?) and adult product looks forward to its cellular dissolution. Certainly if, as in a reversed, cinematograph picture, our life history were suddenly reversed, we would most assuredly look with dread upon the process of a gradual return to youth, childhood, infancy, and intrauterine existence. At least we do not have that sort of thing to contemplate and we can believe that though this life is good "there is better than it" somehow, somewhere, for, while there is constant change, there seems no such thing in Nature as extinction.

CONSTIPATION

The medical profession is as changeable in its teachings and practice as—well, as a woman. One day it condemns constipation, describes resulting autointoxication and urges the regulation of the bowels by suitable foods rather than drugs. The next day it announces that constipation seldom exists, that there is no such thing as autointoxication and recommends the use of laxatives and enemas instead of right diet.

Perhaps we should not say that this veering, weathercock fashion has taken place in the profession, but in some of the profession—those that accept without reserve the conclusions of Alvarez and Freedlander.

It is a good thing that the medical man is capable of change of mind without notice, provided there is ample cause for change of opinion. "One little fact," to quote Huxley, may easily upset the finest spun theories, and its revolutionary power deserves to be recognized. We question, however, whether the results of any single experiment often, if ever, deserve such recognition, particularly when it is carried out in an unnatural way. Glass beads are not food, no matter how small they may be, and their passage through the alimentary canal can hardly serve as a test of the time taken by real food in its passage. Food of one kind is much longer leaving the stomach than that of another kind and we do not know but that the intestine may also discriminate to an extent in this way. We certainly have no knowledge as to how it should behave toward such foreign bodies.

Whether there is or is not autointoxication from retained food substances in the bowels, these experiments certainly do not prove much nor do they in the least disprove that constipation is the most common and most troublesome of human diseases after

carious teeth. Doubtless too much is made of it by many persons who are too thoughtful of their health or are the victims of the internal bath cult, and it is going rather strong to advise, as appears in one health book, "three movements a day." Life is too short for that sort of thing, but, on the other hand, there must be no putting off of "that inclination," for the consequence, whether from autointoxication or what not, is bad from every point of view, even if it does not lead to hemorrhoids, from which condition deliver us!

There may be no such thing as autointoxication, but we would better make certain of the fact, since we have latterly made so much of it, before kicking it overboard. There is, however, constipation and plenty of it, and most of it can be cured by a return to natural ways of behavior toward the whole alimentary canal, and particularly with regard to considering the evacuation of the bowel, at the appropriate time, as of as much importance as filling it up. In this connection it is most significant that constipation is practically unknown in wild animals in captivity. The activity of such animals is certainly not so great or so varied as it is in the wild state and consequently the food consumption is less. Those who have studied the subject most carefully attribute this healthy state of affairs to the fact that such animals are never overfed, that their food is made approximate in quality to the natural diet, but more especially to the fact that the animals always obey the call for emptying the bowel when that call comes.

FOOD ALLERGENS AND ARTHRITIS

To improper diet, to an inadequate or an excessive diet, or to errors of diet of one kind or another are ascribed many of the ills to which human flesh is heir. Diet has a great influence on the production and exaggeration of the symptoms of many diseases and judicious dietetic treatment will abate these symptoms. There are also certain foods to which certain individuals have idiosyncrasies.

In the *Boston Medical and Surgical Journal,* September 4, 1924, John A. Turnbull discusses food allergens in connection with arthritis, pointing out that it has been known for a long time, that in some persons the eating of certain foods would produce rheumatism, as well as disturbances of a respiratory or dermatological character. For instance, strawberries, red meats or some other foods will produce or are believed to produce rheumatism in those predisposed. Turnbull points out that in some cases this belief is founded on, while in other arthritic cases, the statement is the result of sayings which have become traditional, that red meats and acid fruits will produce arthritis in those having a rheumatic tendency. His experience with anaphylactic disturbances of the respiratory tract, such as vasomotor rhinitis, hay fever, asthma and bronchitis, taught him that many of these cases had associated joint manifestations, and, with the elimination of the offending allergens, the arthritis cleared up.

Turnbull gives an account of four cases which came under his personal observation and which, while the arthritis attacked different parts of the body, were all completely relieved by the elimination of the form of diet to which the patient was hypersensitive.

The following conclusions were drawn: 1. Food allergy is an important factor to be investigated as well as other sources of arthritis. 2. A diet should be worked out for each person, the diet of each depending on his own individual sensitization. 3. By the elimination from the diet of the foods to which these patients were sensitive, the progress of the arthritis was arrested, and they were relieved from the joint pains. 4. Elimination of the food allergens produced changes in the articular and periarticular adhesions, allowing increased movements of the parts, which was a great advantage to the patient.

It has been denied by some authorities that diet plays any part in exciting or aggravating the symptoms of arthritis, and yet examples are numerous in which arthritis is intensified by eating certain foods and relief is experienced by refraining from such foods. Is the arthritis associated with such anaphylactic disturbances as hay fever and asthma of a different type from that which is not thus associated; or are the skin or respiratory complaints associated with arthritis but manifestations together with the arthritis of anaphylactic origin? Is the belief of our fathers that certain foods, and especially strawberries and red meats, excited arthritic or rheumatic symptoms, as they termed them, an altogether mistaken one? There is much yet to be learned with regard to the sensitiveness of individuals to particular foods and a study of arthritis suggests itself in this connection. It is a comparatively untilled field and should yield a bounteous harvest, if assiduously cultivated.

THE OVERWEENING VANITY OF YOUTH

Life is being prolonged and some youthful persons have been dilating recently on the wickedness of such prolongation. It is argued that there is no room nowadays for old or even elderly people and that the health measures which are responsible for lengthening the ordinary span of life considerably are neither for the good of the race nor for the individual, and especially are not for the good of the race. It is said

by these opponents of long life that fifty is a suitable age at which to be cut off, more particularly as in overcrowded lands, in Europe for instance, persons above this age are really cumberers of the ground who make it hard for the younger generation to earn a living.

However, this is a creed thoroughly believed in in this country, where gray hairs are frequently an obstacle to obtaining employment, and where the call of youth is most energetically proclaimed. To some extent, this attitude towards age is a natural attribute of youth and can be understood. Youth possesses the vanity and selfconfidence of ignorance and is likely to be supercilious and sceptical of the value of experience. There is another aspect of the question. Old age is relative, one individual may be old at fifty and another of the same age comparatively young. It is above all a matter of health. If the man or woman of fifty or more is healthy there is still the capacity for work and enjoyment. In some vocations, in that of medicine for instance, experience is of the greatest importance, and it is obviously a false statement that life cannot be enjoyed after the age of fifty. It may be pointed out that many young people suffer from hopeless ill health and many elderly people enjoy splendid health. As long as good health is maintained there is room for the old and elderly. As the country proverb, attributed to an English writer in 1539, puts it, "The young men think that the old men are fools; the old men know that the young men are."

THE VALUE OF CODLIVER OIL

Codliver oil is highly valuable both as a food and as a medicine. During recent years, and especially since foods have been studied scientifically, codliver oil has been reinstated completely in the estimation of the medical profession and the public, and the high esteem in which it was held by the older generation of medical men has been justified entirely by modern research.

While doctors of bygone days knew little of the chemistry of food and were wholly ignorant of vitamines and of the necessity for the presence of these and other constituents of food in more or less proper proportions for the establishment and maintenance of good health, they seem to have arrived by observation at many wise conclusions with regard to diet. What they lacked in accurate and scientific knowledge with respect to drugs and foods they made up by their powers of acute clinical observation which were accentuated and intensified by the teaching and practice of long experience. At any rate they made no mistake concerning codliver oil and their dictums as to its therapeutic and dietetic value are daily being borne out by scientific investigation. For example, one of its beneficial therapeutic effects is its use in the treatment of exophthalmic goitre owing to its minute content of iodine, whereas larger doses of iodides are almost invariably harmful.

This fact was again pointed out in a remarkable article on the effect of iodine on hyperthyroidism in man, by S. J. Cowell and E. Mellanby, which appeared in the October number of the *Quarterly Journal of Medicine*. Of course, its therapeutic action is manifested in many ways. As for the antirachitic properties of codliver oil, which are among its most valuable characteristics, it is pointed out by an editorial writer in the *Medical Press and Circular*, November 26, 1924, that these properties are due to some subtle essence and not to the oil considered as merely so much energy yielding material. This is shown by the fact that its antirachitic properties are inactivated by oxidation.

This writer goes on to demonstrate that recent experiments suggest that more than one form of fat soluble A vitamine may exist. It is important also to note that this vitamine, though inactivated by oxidation, can withstand long exposure to a high temperature. A due supply of vitamine A is doubly needful during the years of growth. A deficiency of it favors the occurrence of tuberculosis, rickets, pellagra, renal calculus and xerophthalmia.

Attention may be further drawn to the fact that, as in the case of the other vitamines, it is incapable of being synthetized by the body, but it can be stored for a considerable time within the tissues.

Codliver oil in many respects should be the most highly cherished remedy in the armamentarium of the physician. It is the most easily digested of fats and on account of its great nutritive qualities may be looked upon more as a food than a drug. And it not only facilitates digestion and augments the blood corpuscles whereby the weight of the body is increased but a stimulus is given to healthy cell formation, which depends, to some extent, upon fat supply. Moreover, it is a valuable expectorant. As said before, however, its remedial and even curative properties hinge mainly on its nutritive effects and the many diseases for which it appears to act as a specific are caused by some deep seated error of assimilation which is removed by its continued use. Hence the slowness of its action in cases of chronic rheumatic arthritis, lupus, psoriasis, and so on. Really, owing to the absorption of food elements not usually finding their way into the lacteals by means of cod liver oil, it nourishes the body independent of its own highly nutritious qualities.

The older generation of medical practitioners prescribed codliver oil somewhat empirically, because

although ignorant of how it acted they knew it exerted good effects in certain forms of disease. Their judgment based upon keen clinical observation has now been shown to be scientifically correct and affords another strong argument why scientific methods should be reinforced by clinical experience. There seems to be a too great tendency nowadays to rely upon laboratory methods and to allow the clinical side of the question to lapse. Knowledge of the practical aspect of disease is, at least, as valuable as the strictly scientific aspect, indeed many good judges hold that clinical experience is of the first importance and that the value of the laboratory is that it supplies a useful, perhaps essential, adjunct.

COPROLOGICAL SIGNS OF COLITIS

A colitis can be detected in a coprological examination by direct evidence given by products of the mucosa such as pus, leucocytes and blood. Mucus does not appear to have the importance generally attributed to it. It is merely a banal sign of irritation of the mucous membrane, and it is only when the mucus is cloudy and containing many cells and leucocytes that it is an indication of a deep seated lesion.

More importance is to be given to what Goiffon calls mucoid piles. In stools diluted in a mortar and examined microscopically, these appear as small coherent viscous masses having hardly any consistency and easily broken up with a needle. They often occur in mucous colitides in which the presence of real mucus is most uncommon.

Dissolved albumen, often transformed into albumoses, is an important evidence of colitis and can readily be discovered by the acetic sublimate reagent of Triboulet. These albumoses are not derived from food, but are secreted by the walls of the intestine, hence revealing a morbid change in them.

Diarrhea may be due to a too rapid evacuation of the feces without any lesion of the intestinal mucosa. In these circumstances the stools may contain cellulose, starch and other materials, which indicate an incomplete digestion. On the other hand, the liquid stools may be homogenous, giving a dry residue in lesser amount than normally and contain no product of the digestion. These are stools that have remained in the intestine for a time sufficiently long for digestion to be complete, while the excess of water is evidence of colonic hypersecretion which is generally seated on the left. This pseudodiarrhea may be homogenous, that is to say, perfectly fluid. It may be composed of both solid and liquid matter.

The organic acids are derived from fermentation of the carbohydrates of the food and they increase in direct ratio to the fermentation, but their increase does not of necessity indicate the existence of a lesion of the mucosa. On the other hand, when the organic acids are in lesser amount than normal, it indicates a cessation of fermentation resulting from alkaline hypersecretion or early fermentation going on in the right colon. In both cases a colitis exists. Ammonia is a residue of putrefaction. Unfortunately, it is too readily absorbed by the mucosa, which greatly reduces the value of its doses in the stools. In the microbic intestinal flora, the presence of many spirillæ and blastocytes is evidence of colitis, while the presence of numerous cysts of entameba coli may lead one to presume that colitis exists.

Another sign of colitis, according to Goiffon, is the presence of starch, which can be stained blue in a well formed stool and appearing to have been perfectly digested. Hypersecretion of the right colon —a sign of colitis—prematurely arrests digestion of starch by alkalifying the contents of the cecum.

INFANT WELFARE

For the second quarter of this year, the Registrar-General for England and Wales showed in his return of vital statistics that the infantile death rate was sixty-six per thousand, or eighteen per thousand below the average. This is the lowest infantile death rate ever recorded in England in any second quarter. On the other hand, the statistics revealed a decrease in the number of births during the same period, and as a matter of fact, with any second quarter recorded previously except during the war. In spite of the decrease in the number of births, the population increased by eighty-three thousand, that is, two thousand five hundred more than the increase during the second quarter of 1922.

No doubt the cool weather, the absence of flies and the fact that there was no infectious disease had a great deal to do with this result, but probably the main cause was the work done by the welfare centres throughout the country. The education of the mothers in the art of rearing children has been a very influential factor. There are now in England more than two thousand welfare centres, and the decrease in the death rate has coincided with their establishment. At the beginning of the century there were no such centres, and infants then died at the rate of over one hundred and fifty per thousand. Although this is a vast improvement, two outstanding problems, however, remain to be solved, one, the preponderating death rate of infants during the first month of life, the neonatal period, and the other, the heavier death rate of male infants as compared with female infants. More male are born than female infants, but death takes a heavier toll of the males during infancy and throughout life.

Recently tables published by American insurance companies tend to question the female mortality as evidenced by these tables. But, in a general way throughout the world, the female is longer lived than the male. The reduction of the neomortality would seem to be a problem of the care of maternity, the reduction of the male infant mortality a problem of scientific motherhood. Of course, both are branches of infant welfare.

Indeed the care of the expectant mother is perhaps the most important phase of infant welfare. This question was most carefully considered and discussed at the Infant Welfare Conference held in London a short time ago. The need for maternity homes in all parts of the country was insisted upon. Sir George Newman, Chief Medical Adviser to the British Ministry of Health, in a memorandum published recently, also laid particular stress on the same point, and Dr. Rhoda Adamson at the Infant Welfare Conference discussing the Maternity Resolution of the Washington Convention, 1919, pointed out among other things that the birth of children may be considered from two entirely different points of view.

First, it may be considered to be an entirely family matter brought about to satisfy the desire for a family by the partners in a happy marriage. Second, it may be looked upon as a duty to the State undertaken by certain individuals and not by others. Of course in actual practice both points of view come into consideration. While many children are born because their parents want them, and are able and anxious to care for them, the State has need of every child born into the country and it is argued should take responsibility for it when the parents are either unable or unwilling to care for it. Obviously of the two parents the mother has the more immediate influence upon the health of her unborn and newly born child than the father.

If the mother is overworked and underfed she becomes weak and anemic and the child is born handicapped by a lowered vitality. After birth, too, she is not in a sufficiently good physical condition to nurse and rear her child properly. It is patent that for an infant to be born under favorable conditions the expectant mother must be well nourished both in body and mind, that the mind should be at ease is hardly of less consequence than that the body should be in good condition. Now these essentials are not possible if the mother has to work and worry while pregnant and does not get enough proper food. In many cases the expectant mother has to undergo these drawbacks with the result that the infant is handicapped from its very birth. This is contrary to the best interests of the individual, society and the State and it would seem that it is to the advantage of all that the State should take the responsibility of caring for mother and child. Moreover, every expectant mother should have the care of a properly trained obstetrical attendant during her pregnancy, labor and lying-in period. If this were so there would be fewer cases of stillbirth and damage to the child at birth and less burden of ill health during expectant motherhood and danger to life and health resulting from want of care during labor.

This adequate skill and care should not be a question of money but of the condition calling for it. Naturally payment for leisure from industrial work and paying for adequate maternity care cost much money. But according to the arguments of a large section of the medical profession and of the public money thus spent will be money well spent as it will be very much less costly in the long run than the continued responsibility by a country for damaged and badly developed children grown to maturity. The good health of its population is the greatest asset of a nation, and for adults to be healthy they must be born and reared under favorable conditions. Infant welfare efforts have been attended with great success so far and if extended wisely in the directions pointed out should have proportionately greater success.

SEMIANNUAL INDEX

The index to Volume CXX of the MEDICAL JOURNAL AND RECORD, July to December, 1924, is now ready for distribution. Readers who desire a copy of this index may receive it on request.

News Items.

Goitre Survey.—The state department of health of Illinois is endeavoring to work out a practical plan for a goitre survey of the state.

Intern Appointments.—An agreement has been reached by fifty-eight of the Philadelphia hospitals to make no arrangements for appointment of interns before February first of the student's senior year.

Industrial Hygiene Survey.—The Philadelphia Health Council and Tuberculosis Committee has completed a study of the extent of industrial health service in that city.

New Cottage at Trudeau Sanatorium.—A cottage for women who have incipient tuberculosis has been built at Trudeau Sanatorium, as a memorial to Arthur and Susan Gillender.

Research in Anemia.—An endowment of $400,000 has been received by the University of Michigan, through the generosity of Mrs. Christine MacDonald Simpson, to be devoted to research in pernicious anemia.

Gift to Institute for Crippled and Disabled Men.—Announcement is made of a gift of $200,000 from Jeremiah Milbank to the Institute for Crippled and Disabled Men, the income to be used in industrial training.

Pasteur Memorial.—Dr. Frank Billings, of Chicago, is chairman of a committee working to raise a fund of $100,000 for a monument to Pasteur, to be erected in Chicago, and a research scholarship, open to all American students.

Memorial to Dr. Southard.—A bronze tablet, designed by Bashka Paeff, has been placed in the Boston Psychopathic Hospital, in memory of Dr. Elmer Ernest Southard, the founder and first director of the hospital. Dr. Southard died in 1920.

Harvard Medical Dormitory.—Dr. Francis M. Rackemann is secretary of the executive committee of the Harvard Medical School Dormitory Fund, which is endeavoring to raise funds for a new dormitory. The sum of $250,000 has already been raised.

Coast Water Pollution.—Mr. D. M. Neuberger, of New York, president of the National Coast Antipollution League, is endeavoring to have legislation passed safeguarding the navigable waters around the city from pollution, by land plants as well as floating craft. At present naval vessels and vessels of the shipping board are excepted in the law.

Extension Medical Work.—The alumni of the University of Georgia Medical Department are planning to give a series of extension courses on internal medicine, physical diagnosis, pediatrics, and sanitation, in cooperation with the various county medical societies. The courses will be given in localities where there is clinical material available, and will be open to all physicians; the expense will be borne by the university.

Civil Service Examinations.—Examinations will be held in Washington, Chicago, New Orleans, and San Francisco, on March 2d, for entrance to the regular corps of the U. S. Public Health Service. Candidates must be between the ages of twenty-three and thirty-two, graduates from a reputable medical school, and must have had one year's hospital or two years' professional experience. Details should be obtained from the Surgeon General of the U. S. Public Health Service.

Examinations will be held beginning February 18th, for physiotherapy aide, physiotherapy pupil aide, and physiotherapy assistant, for vacancies in the U. S. Veterans' Bureau. Details should be secured from the U. S. Civil Service Commission.

Hospital News.—The four-story fireproof building at the corner of Twenty-first Street and Second Avenue, recently acquired by the New York Post-Graduate Medical School and Hospital, will be formally dedicated to its new use at 4:30 on the afternoon of Thursday, January 22nd. Among the speakers will be Dr. Livingston Farrand, president of Cornell University; Rear Admiral E. R. Stitt, chief of the Bureau of Medicine and Surgery; Dr. Augustus S. Downing, first assistant commissioner of education and director of professional education of the State of New York; and Dr. Henry Dwight Chapin, for many years a member of the Board of Directors of this institution.

The first contracts in connection with the construction of the new Columbia Presbyterian Medical Centre have been awarded to Post & McCord for the steel work of the new Presbyterian Hospital and the new building to house the College of Physicians and Surgeons. The contract also includes the Presbyterian Hospital private patient pavilion. The combined cost of the Hospital and Medical School building has been fixed at $10,000.000. This is the first of the group of hospital and school buildings to be erected on the twenty-acre site of land at 168th Street overlooking the Hudson River.

Society News.—At the meeting of the American Stomatological Association, to be held February fifth, 8:30 p.m., at 50 West Eighty-eighth Street, Dr. Samuel I. McCullagh will speak on "Rhinology in Relation to Stomatology, with Special Reference to Chronic Antral Infections." Discussion will be by Dr. Louis A. Coffin, Dr. Edward S. Pope, and Dr. Ferdearle J. Fischer.

The Medical Society of the County of Kings elected the following officers for 1925 at its annual meeting held December 16th: Dr. John E. Jennings, president; Dr. O. Paul Humpstone, vice-president; Dr. Thomas M. Brennan, secretary; Dr. James Steele, associate secretary; Dr. Charles H. Goodrich, treasurer; Dr. Eliot Bishop, associate treasurer; Dr. William Browning, directing librarian; Dr. Jacques C. Rushmore, associate directing librarian and curator; Dr. Charles A. Gordon, trustee; Dr. Henry Joachim, Dr William V. Pascual, Dr. Robert F. Barber, Dr. Thurston S. Welton and Dr. Howard T. Langworthy, censors. The following delegates to the Medical Society of the State of New York were elected for a term of two years: Dr. Edwin A. Griffin, Dr. Charles E. Scofield, Dr. Claude G. Crane, Dr. Henry Joachim, Dr. John J. Masterson, Dr. George D. Hamlin, Dr. Russell S. Fowler, Dr. Roger Durham, Dr. John J. A. O'Reilly, Dr. Harry H. Patrie, Dr. Charles A. Gordon and Dr. Richard A. Henderson.

Personal.—Dr. Norman E. Titus has been appointed associate in surgery at Columbia University, to have charge of the physiotherapy instruction.

Dr. Philip Ingram Nash was the guest of honor at a banquet in recognition of his effective civic activities.

Dr. Seth R. Sprague is the new chief of the orthopedic clinic of the Jersey City Hospital, succeeding the late Dr. Henry Bogardus.

Dr. Abraham Strachstein, retiring president of the Eastern Medical Society, was the guest of honor at a dinner at the Hotel Commodore. He was presented a gold watch in recognition of his services. The incoming president, Dr. Nathan Ratnoff, acted as toastmaster.

Dr. Charles H. Mayo, of the Mayo Clinic, has endowed a lectureship in surgery at Northwestern University Medical School, Chicago.

Dr. George W. Alexander, of Gardiner, Maine, has been appointed a member of the state public health council, succeeding the late Dr. Frank N. Whittier.

Dr. Alfred Worcester, of Waltham, Massachusetts, a former president of the Massachusetts Medical Society, was the guest of honor at a testimonial dinner.

Dr. Arthur C. Bachmeyer, superintendent of Cincinnati General Hospital, has been appointed dean of the University of Cincinnati College of Medicine, succeeding Dr. Henry Page—effective next September. Dr. Bachmeyer is president elect of the American Hospital Association.

Dr. George E. de Schweinitz, of Philadelphia, has been elected a trustee of the University of Pennsylvania.

Dr. Alexander M. Burgess of Providence has been appointed medical director to Brown University.

Dr. E. D. Friedman, who is attached to the staff at Bellevue and Mt. Sinai hospitals, has been appointed clinical professor of neurology in the Medical Department of New York University.

A testimonial dinner was tendered to Dr. L. Duncan Bulkley, on Monday evening, January 12, 1925, at the Hotel Astor, to commemorate his eightieth birthday and fifty-six years of the practice of medicine.

Dr. Harvey C. Hullinger, of Vernal, Utah, celebrated on December 2, 1924, his hundredth birthday. Dr. Hullinger is still in practice.

Dr. Alice Hamilton, of Harvard University Medical School, has been appointed a member of the health committee of the League of Nations. Dr. Hamilton has recently returned to this country from a study of health conditions in Russia.

Dr. George A. Wingate, of Brooklyn, and Dr. Thomas W. Salmon and Dr. Henry A. Cotton, of New York, have been appointed by the U. S. Veterans' Bureau to select a site for a neuropsychiatric hospital to be built in the district of New York, New Jersey, and Connecticut.

Dr. Hugh J. Morgan, of Baltimore, who has been on the staff of Johns Hopkins Hospital, has been appointed associate professor of medicine at Vanderbilt University Medical School.

Dr. Jacob C. Price, director of the state board of health of New Jersey, has resigned on account of ill health, and Dr. Henry B. Costill, of Trenton, has been appointed his successor.

Dr. Solomon Metz Miller, for many years chief resident physicians of the men's division of the Norristown State Hospital for the Insane, Norristown, Pennsylvania, has been appointed superintendent.

Dr. Mabel E. Elliott has been appointed to the staff of the Woman's Medical College Hospital, of Philadelphia. Dr. Elliott was for several years director of American Relief Work in in the Near East and Caucasian Russia.

Dr. Coleman B. Ransone has become health officer of Roanoke, Virginia, resigning from his position as head of the department of health of Newport News.

Dr. John E. MacKenty, of New York, discussed the subject of artificial larynges at a recent meeting of the Otolaryngological Section of the Baltimore City Medical Society, presenting four patients for whom the appliance had been made.

Dr. Jacob Sobel, of New York, has been appointed assistant attending pediatrist to the Metropolitan Hospital.

Dr. J. L. McElroy has resigned as superintendent of the Ancker Hospital of St. Paul, Minnesota, and will become superintendent of St. Mark's Hospital, New York.

Dr. Frederic W. Bancroft, of New York, has been appointed surgical director of Lincoln Hospital.

Foreign Correspondence

LONDON LETTER

(From our own correspondent)

London, *December 2, 1924.*

ANNUAL REPORT OF LONDON COUNTY COUNCIL

Sir William Hamer, Medical Officer of Health for the County of London, states in the annual report of the London County Council that the deaths from tuberculosis of the respiratory system in London during 1923 numbered 4,432, giving a death rate of 0.9 in a thousand. Deaths from other forms of tuberculosis numbered 553, as against 936 in the previous year. The decrease in the tuberculosis death rate in 1923 is considerable, and indeed is greater than in any year since 1910, if the abnormal years of the war period be excluded. An analysis of the age distribution of deaths from phthisis indicates a decrease which is most marked at the principal ages of influenza mortality; the inference is drawn that the decline in phthisis mortality must be ascribed at least in part to the absence of any epidemic prevalence of influenza in 1923. The number of notifications of tuberculosis in London during 1923 was 12,175, as against 11,548 in 1922. Reference is made to a paper by Dr. L. I. Dublin, statistician to the Metropolitan Life Insurance Company of New York, on the causes of the decline of tuberculosis, analyzing the evidence in support of two distinct theories. The first theory emphasizes more especially the importance of environmental factors in the causation of tuberculosis; the second emphasizes the importance of stock and ascribes the decline to changes in the germ plasm of nations and of races. Of these two explanations the first is believed by Dublin to be the true one. A most interesting and suggestive part of Sir William Hamer's report is that in which he discusses encephalitis lethargica. With Crookshank and others he does not believe that it is a specific disease but summarizes the evidence in favor of the identity of encephalitis lethargica with influenza.

The number of cases of tuberculous children who were under treatment on December 31, 1923, was 707, and the total number treated during the year was 1,404. In addition to the provision for treatment of tuberculous children in residential institutions, the council continued the use of five open air schools. A summary is given of the results of the inquiry conducted by Dr. Bardswell as to the after histories of adult tuberculous patients in the County of London who received institutional treatment during the year. This inquiry has confirmed the existing impression as to the usefulness of the sanatorium in the treatment of tuberculosis in its initial stages, and of its ineffectiveness when the disease is well established. According to the report, there appears to be no doubt that the patient's home environment, his housing, work, habits, temperament and standards of living determine the consumptive's future to a much greater degree than does his period of sanatorium treatment. Under the conditions to which many, indeed the majority, of London patients return on leaving a sanatorium, well established tuberculous disease of the lung is rarely to be cured. Successfully to withstand conditions so unfavorable, tuberculosis must needs be arrested more completely than is possible during a stay of a few months in a sanatorium. A year's continued sanatorium treatment might make more difference. Even then, in many cases, one would expect bad home conditions to be the decisive factor in ultimate failure.

CONGRESS OF THE ROYAL SANITARY INSTITUTE

The next Congress of the Royal Sanitary Institute and Health Exhibition will be held in Edinburgh from July 20 to 25, 1925, by invitation of the Magistrates and City Council.

MEDICAL REPRESENTATIVES IN PARLIAMENT

Twelve members of the medical profession have been elected as members of Parliament. Three of these are in general practice, three represent universities, and the remaining six have given up medicine. Seven are Conservatives, four Labor, and one Independent.

PERSONAL ASPECTS OF PREVENTIVE MEDICINE

Sir George Newman, chief medical officer of the Ministry of Health and of the Board of Education, has written and issued recently a report dealing with public education in health. Discussing the personal aspect of preventive medicine, he points out that a great cause of sickness is digestive disturbance, which is frequently due to errors of diet. Many an individual compels his stomach to work overtime, at irregular intervals and at inordinate speed; or he consumes ill balanced, monotonous mixtures of indigestible food: the real needs of the organism he makes subservient to demands of convenience, habit or fashion. Even if he tries to eat the right thing at the right time, he does not know that milk, butter, vegetables, fruits and numerous other foods are preserved, colored or adorned by the addition of substances which may be harmless, but, on the other hand, may be definitely injurious. Even flour may have a large amount of its valuable nutrient removed, and be treated with various undesirable chemicals to make it white and pleasing to the eye. Knowledge of food values and the needs of the body is lacking, with the result that much money is spent on unsuitable food, while many valuable and cheap foods are almost entirely neglected. Only by teaching individuals, what, when and how to cook and eat, and how to protect their food from contamination, can the digestive system be ensured of the respectful and considerate treatment that will enable it efficiently to fulfill its function. The diet should be as far as practicable sufficient, varied, nutritive and digestible. Overeating and overdrinking and swallowing food without proper mastication should be avoided. On the whole, Sir George Newman thinks that there are grounds for believing that there is no single subject of more importance to personal and national health, or more crying out for educational treatment than this one of the proper use and control of food. According to Professor McCollum, of Johns Hopkins University, the chief factor re-

sponsible for human deterioration in recent times is the unwise choice of food. Much can be achieved through dietary reform.

The crippling of children by rickets or bone tuberculosis are other conditions of ill health referred to. It is pointed out that the first of these is now known to be preventible, and is due almost entirely to faulty feeding and rearing in the early years of life. It is likewise known that it cannot be prevented without correct feeding, sunlight and fresh air. Bone tuberculosis, even after the disease has appeared, can to a great extent be prevented from crippling its subject if early and appropriate treatment is given.

Sir George Newman particularizes ten types of conditions or disease which lead to chronic ill health, crippling or death, and which are responsible for the greater part of the mortality and suffering of civilized life, and which, as he insists, for their remedy demand personal knowledge and personal practice. He emphasizes the fact that in the existing situation only an educated people is an effective people. It may be further added that in the existing situation in all parts of the civilized world this statement applies with equal force. Moreover, it is the women and mothers who chiefly need education with regard to diet for it is women who have the care of the children.

VIENNA LETTER

(*From our own correspondent*)

VIENNA, *December 2, 1924.*

THE DISCOVERY OF CANCER PRODUCING BACTERIA

The Society for the Study of Digestive and Metabolism Diseases in Berlin held a conference the last of October. In the session on the twenty-third, Dr. Ferdinand Blumenthal, secret councillor, reported that he had succeeded in discovering the causal agents, that is, the bacteria of cancer, which have the power of producing cancer in an animal. He made pure cultures from bacilli derived from human cancer, and with these produced cancerous growths in animals, which growths are propagating on the same kind of animals and which ulcerate and which are equal to the cancer growths, biologically as well as histologically. Up to the present he had succeeded in cultivating two different growths, up to the ninth generation. In order that the growth shall develop, it was necessary to give a stimulating preparation. This fact shows that beside the inner disposition an external stimulus is necessary to cooperate in the production of cancer. Blumenthal is modest enough to confess that he did not discover the causative agent of cancer, but only a group of cancer producing bacteria.

WASSERMANN ON THE DIAGNOSTICS OF CANCER

At the same meeting Professor Wassermann, secret councillor, gave a lecture on the diagnosis of malignant tumors. He started out from the fact that there is one specific causal agent, which is capable of producing specific changes in the blood. Experiments had been made to discover these agents which produce cancer, but up to the present it had been only possible to state that cancer was caused by parasites, but on the other hand that it could occur without these. By reason of this serodiagnosis is impossible from a bacteriological viewpoint. Otherwise it would be possible to make specific reactions as is the case with syphilis, with the assumption that cancer cases behave, from a biological and biochemical point of view, differently as the body cells. In order to answer the question of difference let us reflect that the fetus in the womb of the mother is biologically a special individual, and from this fact it can be concluded that the cancer cells also behave differently from the cells of the host. Up to now, however, it was possible to verify quantitative differences, but not qualitative ones. Professor Wassermann believes that in the near future he will succeed in confirming such differences, too, so that there will be a prospect of building up the diagnosis and therapy of cancer.

ULTRAVIOLET RAYS IN LARYNGEAL TUBERCULOSIS

The recent meeting of the medical society was opened with a memorial speech by Professor Maresch to the late Professor Paltauf. Afterwards Professor Hajek and his assistant, Dr. Wessely, spoke about the actinic therapy of the diseases of the upper air passages. Tuberculosis of the larynx was first described by Vienna doctors, namely, Stork and Schrötter. This very serious disease was first treated surgically, but the unsatisfactory results achieved by this method have compelled the laryngologists to consider other methods. They tried to heal the small ulcers by burning them with galvanocaustic. Later on the inhalation treatment with antiseptic sprays was resorted to, but the result was no better. Also the blowing in of iodine and iodoform was tried. As all these procedures were of no avail, the ulcers were cauterized with lactic acid. In 1908 Professor Sorgo succeeded in inventing a device which made possible the direct application of sun's rays into the larynx. He taught his patients to reflect the sun's rays with the aid of a laryngoscope upon the larynx itself, and he succeeded in getting good results with this simple method. In the Vienna clinics, for diseases of the air passages an apparatus has been used since 1920, which produces the ultraviolet rays in a great quantity in order to cure tuberculosis of the larynx. With this simple method excellent results have been attained and Professor Hajek said that he felt encouraged to recommend this method for all cases of tuberculosis of the larynx, as the best one at present.

THE VIENNA HYGIENE EXHIBITION

The Health Board of the Austrian state, in conjunction with the Board of Health of the City of Vienna, established an exhibition, comprising all that pertains to the hygiene of the individual and of society, that is to say, the community. A special importance attaches to the fact that the exhibition has been enriched by the abundant collection of hygienic matters which were exhibited in Dresden in 1911 in the vast exposition, called, *Der Mensch*. This collection embraced all articles pertaining to personal and general hygiene. On all these subjects lectures were held and free booklets were distributed. Explanatory films were shown and special courses were held on eugenics.

LATIN AMERICA LETTER

(From our own correspondent)

Balboa Heights, Canal Zone, *December 12, 1924.*

YELLOW FEVER SITUATION IN CENTRAL AMERICA

Dr. Henry Hanson of the Rockefeller Foundation recently passed through the Canal Zone on his way to Colombia, where he will continue the direction of the sanitary campaign which he has been conducting for many months. His work in Colombia was interrupted some time ago by the outbreak of yellow fever in San Salvador. Since July, he has been carrying on a campaign against yellow fever in that city. During a recent conference with the Chief Quarantine Officer of the Canal Zone, Dr. Hanson said that since the first case of yellow fever in San Salvador in June there have occurred eighty cases with thirty deaths. He saw thirty of the cases and was present at seven autopsies. In the hotel at which he stayed five Americans were taken with the disease. Among these was Mr. L. H. Dunn, one of Dr. Hanson's staff. He had previously been inoculated with the Noguchi serum for yellow fever, but contracted the disease before immunity had been successfully established. The entire American colony has been immunized with this serum. No new case of the disease has been reported since November 14, 1924. Dr. Hanson says that although the epidemic seems to have been controlled and the campaign is actively continuing, the survey has not yet been concluded upon which data could be based for estimating eradication of the infection. Ahuachapan, El Salvador, also reports the disease.

Just at the time it was thought that yellow fever was being eradicated from the Central American states a report was received to the effect that it had broken out in the Stann Creek district of British Honduras. A quarantine embargo against ports of British Honduras has been issued.

WAR ON CHIROPRACTORS IN COLON

Medical practitioners in the City of Colon have complained to the Mayor of the increasing number of chiropractors who, they say, not only employ their own methods but enter the realms of practical medicine, although not qualified either by license, experience or study to do so. The physicians ask that if these men desire to practice modern medicine they first pass an examination before the National Board of Hygiene. Prior to taking action on the matter, it was submitted by the Mayor to the National Board. In reply, the chairman of the board quoted Article 20, Law 18, of April 6, 1904, which specifies that any person desirous of practising medicine or surgery in any of its branches must first pass an examination before the board in the manner and form it may prescribe. The Mayor therefore dictated a resolution to the effect that all chiropractors doing business in the city of Colon must appear before him and be notified that before practising further they must take an examination before the National Board of Hygiene, and pending the result of such examination, must remove all signs and other business announcements from their offices. In case the applicant passes the examination he will be so notified and permitted to continue his practice.

PANAMA SCHOOLS CLOSE ON ACCOUNT OF INFLUENZA

All schools in the City of Panama were ordered closed in November due to the alarming increase of influenza cases among the residents of Panama, and as a means of preventing the further spread of the disease. In the Canal Zone the disease is on the wane but a few weeks previously the schools were almost depleted. The order closing the schools in Panama was issued by the Acting Inspector of the Panama Schools, who addressed a circular letter to all principals. They will remain closed until the epidemic abates. The schools of the Zone were not closed because the Health Department believes that better control can be effected when the children are in school.

SERVIA HONORS TO FORMER CANAL ZONE SANITARIANS

Dr. Luis de la Pena and Mr. Otis Campbell, two former sanitary inspectors of the Canal Zone during the construction days, were recently decorated by the King of Servia in recognition of their services several years ago with the American Red Cross during a campaign against typhus fever in that country. They were decorated with the Order of Saint Sava. Mr. de la Pena lost his life a short time ago in Nicaragua, where he was carrying on a sanitary campaign. Both of these men worked directly under General Gorgas during construction days and later Mr. Campbell left to engage in sanitary work in several South American countries. To receive the order of Saint Sava is an honor of the highest sort. In Servian history, Prince Rastko, the youngest son of Stephen Nemanya, who in the early part of the twelfth century united all the Serb countries under his rule, secretly left his father's court and entered the famous Monastery of Mount Athos. He became a monk, discarded his paternal name, and was known as Sava. St. Sava became the first Archbishop of Servia, established eight bishoprics, and encouraged schools of learning. He is the patron saint and protector of education among the Serbs.

ROCKEFELLER FOUNDATION ACTIVITIES IN CENTRAL AMERICA

A commission composed of Dr. M. E. Connor, Dr. Henry Beeuwkes, and Dr. Henry Muller have started a sanitary survey in Mexico and all Central American countries except Costa Rica, looking toward the banishment of the transmitter of yellow fever, the stegomyia. With the sanitarians, a large staff will make the survey and later will inaugurate an active campaign against the yellow fever mosquito.

HEALTH RADIO LECTURES

The National Health Department of Argentina began in July last the broadcasting by radio of brief talks on subjects related to health; stations LOX and LOZ are being offered for that purpose by the Argentine Association of Radio Culture. The subject matter of these lectures covers a wide field and is directed largely at the improvement of child welfare, the protection of children against tuberculosis, the care of people's mouths, colds and other pulmonary diseases, quackery in the treatment of tuberculosis, the prevention of trachoma, the prophylaxis of syphilis and many other questions of personal hygiene receiving appropriate attention.

Letters to the Editor.

THE CAUSATION OF CANCER

London, *December 1, 1924.*

To the Editor:

I have read your very kindly and rather extensive review of my book *Cancer: How It Is Caused, How It Can Be Prevented,* in your issue of November 19th. While acknowledging that my book ought to do a great deal of good by urging simpler, more natural and more biological living, and while admitting that the reforms advocated by me "will ward off many diseases, perhaps, including cancer," there is a tone of doubt as to whether my analysis of the cancer causes is correct or not. You will therefore be interested in learning that my theory that the disease is due to chronic poisoning and vitamine starvation has received ample confirmation since the time when it was put forward.

Numerous medical men have written to me from far away countries endorsing my view that cancer is a disease of civilization and is practically unknown among primitive races leading primitive lives. The most striking confirmation came to me from Colonel Hallilay, of the Indian Medical Service, who informed me that he had worked during more than twenty years among the Hill tribes of the Himaylayas, that he had performed thousands of operations among the natives who readily and gladly submit to surgical treatment, that he had performed no less than seven hundred operations for stone of the bladder, but that he had performed not a single operation for cancer during all that time, except on Anglo-Indians and on the Europeanized natives of the plain. That is surely a most remarkable fact, to which I would draw the attention of all cancer researchers.

Cancer is obviously a disease of civilization and of luxury. Therefore it is most frequent in the wealthiest districts of England and the United States. In England cancer is least frequent among the very poorly paid agricultural laborers, gardeners and clergymen, who not only have a very sparing diet but are physically very active. Overfeeding and inactivity combined lead to congestion, constipation, autointoxication, gout and a host of diseases. Protein poisoning, due to the wrong teaching of Liebig, is universal among well to do populations. Lately the British Government has published statistics relating to the mental hospitals. They show that the cancer mortality in these institutions is only three per cent., while in England and Wales it is no less than 12.4 per cent. This tremendous disproportion is all the more remarkable as the mental hospitals, with a population of about one hundred thousand, contain few children. Feeding in these institutions is exceedingly plain. Many similar facts might be given, but I do not wish to weary your readers.

A few days ago an acquaintance of mine visited me and told me that he had read my book but that in the case of his wife, who had died a few months ago from cancer, there was no indication of chronic poisoning and vitamine starvation. She had had a regular evacuation every morning, though she sometimes took pills, and she had led a perfectly normal life. A few questions on my part led to the admission that the lady took meat three times a day, that she lived on concentrated and very rich food, that she took practically no exercise, and that the place of retirement was filled with a pestilential smell after she had been there. Obviously the lady suffered from disguised constipation. She had an evacuation every day but the remainders of a dozen meat meals or more were habitually putrefying in her bowels.

I did not mention the important factor of mineral salts in my book and I think I shall make good that omission in the fifth edition which will be required before long. I am well aware of the supreme importance of mineral salts and I know that mineral salts deficiency leads to a great number of diseases. However, I am not satisfied that it is one of the causes of cancer, although the weakening caused by mineral salts starvation may have something to do with it. However, mineral salts and vitamines go together. Refined flour and overcooked vegetables, refined sugar, etc., are deprived of both the vitamines and mineral salts. As I have advocated the use of wholemeal bread, of raw fruits and salads, of conservatively cooked, which means steamed, vegetables and of sugar in its natural condition, I have urged both the high consumption of vitamines and of mineral salts.

J. Ellis Barker.

DOSES FOR CHILDREN

New Haven, Conn., *December 22, 1924.*

To the Editor:

The article by Dr. A. D. Bush on Doses for Children, in the December 17, 1924, number of your Journal adds one more suggestion to the many as to the determination of the proper dose of a drug for a child. He apparently is not familiar with my rule, which to me is the simplest that was ever propounded. I first published this rule about twenty-five years ago, but it appears on page thirty-eight of my book, *Principles of Therapeutics* (1921), with which book Dr. Bush is apparently not familiar.

Of course the most accurate method of determining the dose for a child is its weight. A large child of three years, for instance, will take the dose of a small child of five years.

My rule is as follows, the adult dose being considered at twenty years and upwards:

At twenty years the adult dose.
At ten years, one half the age, one half the dose.
At five years, one quarter the age, one quarter the dose.
At two and a half years, one eighth the age, one eighth the dose.
At one year, one twelfth the age, one twelfth the dose.

If the child's age is between the ages given in the table, a little more or a little less, as the case may be, than the dose called for at the age in the table nearest the child's age will be the dose.

The advantage of this dose table is that it is so simple and so easy to compute. It is correct for determining the dose of all drugs except narcotics. To quote from my book, page 38: "The child's brain and central nervous system are relatively larger to its weight than in the adult, hence drugs that act strongly on the brain should be given in smaller doses than the above table would indicate."

This letter is not meant to criticize Dr. Bush for his omission of my suggestion, but to suggest the most simple rule to determine doses.

Oliver T. Osborne.

Book Reviews

OBESITY

The Cure of Obesity. By Doctor Jean Frumasan. Translated from the French by Elaine A. Wood. New York: William Wood and Company, 1924.

This little book of 124 pages describes the author's procedure in the treatment of the obese. The technic, briefly summarized, is as follows: 1. Purging, to overcome the ever present "intoxication." 2. Fasting for five to ten days to be terminated on the appearance of "true" hunger. During this period the patient is to wear a firm abdominal belt to aid in maintaining the tone and position of the viscera. He is also to receive hydroelectric baths with the current directed through the intestines, liver and stomach; as well as iodized ionization localized over the prominent fat masses of the body (abdomen, hips, back, legs and arms). If we are to take the author literally such fat deposits proceed to melt away rapidly under this treatment. 3. Diet, based on the principle of progressively increasing, sufficient alimentation. During this stage the patient receives intensified physical culture and abdominal massage.

The general plan of therapy seems sound and the remarks on diet appear sensible. It is hard to imagine how such long periods of fasting as those recommended could be accepted by any large number of obese subjects, unless these were under the dominance of an impressive personality. If the electrical results obtained are as startling as is asserted they should soon be confirmed by other workers in this field.

The book is apparently written for the laity, it is difficult to see to what purpose. It should, however, form stimulating reading to physicians, as it is obviously a sincere and courageous effort to popularize a new and fundamental line of therapy for a widespread affliction. Such an end—legitimate medical popularity—would be best furthered in our opinion by a medical rather than by a lay translator, inasmuch as the book shows repeated evidence of unfamiliarity with exact English medical equivalents.

The glossary is carelessly edited.

Uber Wesen und Behandlung der Fettsucht. Von Prof. Dr. S. Isaac, Gegründet von Prof. Dr. Joh. Müller in Nürnberg und Prof. Dr. Otto Seifert in Würzburg. Neue Folge herausgegeben von Prof. Dr. E. Magnus-Alsleben in Würzburg. Neue Folge, Band I. Heft 6. Der Ganzen Reihe 21. Band. Leipzig: Verlag von Curt Kabitzsch, 1924. Pp. 155-188.

In these days of the quest for the "boyish" form, especially on the part of the female sex, a monograph on the nature and treatment of obesity seems to be in order. Two types of obesity are distinguished—exogenic and endogenic. After discussing the metabolic disturbances occurring in obesity, the part played by the endocrine glands (thyroid, genital, hypophyseal, epiphysis, adrenal cortex and thymus) in the pathogenesis is taken up. The treatment includes general dietary regulations and also special types of diet, muscle work, hydrotherapy, courses at watering places, thyroid therapy, operations on hypophyseal tumors, x rays and, possibly, antiluetic treatment.

Nebenwirkungen der modernen Arzneimittel. Erster Nachtrag zur zweiten Auflage des Hauptwerkes von 1923. Von Prof. Dr. Otto Seifert in Würzburg. Neue Folge, Band I. Heft 7. Der ganzen Reihe 21. Band. Leipzig: Verlag von Curt Kabitzsch, 1924. Pp. 189-215.

The most recent therapeutic remedies and their indications are described, including their dosage and byeffects. The bibliography of each remedy is appended. The preparations are mostly of German manufacture and the vast majority of them have not been in use for a sufficient length of time to warrant their adoption. The names of the manufacturers are also given.

DISEASES OF THE HEART

Diseases of the Heart. By Dr. Henri Vaquez, Professor of the Faculty of Medicine of Paris. Translated and edited by George F. Laidlaw, M.D. Introduction by William S. Thayer, M.D., Johns Hopkins Hospital. Illustrated. Philadelphia and London: W. B. Saunders Company, 1924. Pp. 743.

Since its publication in French in 1921, Dr. Vaquez's excellent book has been favorably known to American physicians who are particularly interested in cardiology. The wider reading public among the profession owe Dr. Laidlaw a debt of gratitude for making this splendid monograph available to those who do not read French. Vaquez is the leading French clinician in the realm of diseases of the heart and, as Professor Thayer says in his introduction, "the rare book that presents the life work of one wise man holds for itself a permanent place in medical literature." Dr. Vaquez seized the opportunity of this American edition to undertake a thorough revision of the book. The material is presented in five major sections: 1, methods of examination; 2, the cardiopathies and arterial hypertension; 3, the arrhythmias; 4, heart failure; 5, treatment. The chapter on arterial hypertension is of particular interest for Vaquez has himself made some fundamental contributions to the subject. He holds that hypertension precedes the renal and vascular lesions, a view that is finding ever wider acceptance; but he still clings to the idea for which there is no experimental evidence that it is due to an overactivity of the chromaffin system. It is difficult to select chapters for special commendation, for they are nearly all written with the same finish and accuracy. It is only when the author theorizes as to the mode of origin of the various cardiac disorders that we cannot follow him, for like all French clinicians, he allows his fancy too wide a latitude. However, he is careful to differentiate fact from hypothesis. The chapter on chronic myocarditis is a bit disappointing. Vaquez retains this term for the myocardial degenerations. His presentation of the clinical picture is not up to the standard of the other chapters. Dr. Laidlaw's translation is faithful and fluent. Indeed, on page 149, he even translated a mistake from the original French to the effect that Stephen Hales' pioneer blood pressure studies were made on a dog, when in fact that reverend gentleman conducted his experiments on a mare. The brief but adequate historical summaries at the

beginning of every chapter, as well as the selected bibliographies at their end not alone give a scholarly background to the book, but add greatly to its value. The volume can be recommended as by far the best text book on diseases of the heart that has been published in this country in recent years.

HUMANITY

Manhood of Humanity. The Science and Art of Human Engineering. By Alfred Korzybski. New York: E. P. Dutton & Company, 1921. Pp. xv-264.

We may have been accustomed to think of the distinguishing characteristic of humanity in somewhat more psychological terms than does this present author. Yet we cannot fail to be restimulated to the task to which he so earnestly calls his readers through his novel statement of the problems which our generation has brought us. Korzybski urges manhood to awaken from its previous infancy, which has extended through all the ages. He sets the task of entering into humanity's manhood in the formulas of mathematics, making it a matter of practical engineering to set to work upon the direction and control of real progress. Let us clear ourselves, he says, of the old confusing notions that man is only animal or that he is a hybrid of beast and divine. His place in nature is sufficiently grounded in an evolutionary past and yet exalted enough in its ethical possibilities to justify an emphasis upon his particular capacity, which the author defines as the "time binding" one. This lifts man from mere dominance in space, which he shares with lower creatures. It gives him the possibility of retaining his past and recreating it into new achievements. These achievements are not his mere multiplication in numbers nor the increase of material comforts with which he surrounds himself. The rapid growth of these is in geometrical progression in contrast to the slower arithmetical rate of his more profound and lasting achievements, his truer and deeper creations. This has caused the lack of balance which periodically produces cataclysmic upheavals to overturn civilizations. Recognition of the mistaken conceptions which the writer thus combats and the realization of man's past as thus bound to him, must be the preparation for a more definite building of humanity in the future.

WORK OF AMERICAN QUAKERS IN FEEDING GERMAN CHILDREN

Grösse und Gewicht der Schulkinder und andere Grundlagen für die Ernährubgsfürsorge. Neubearbeitung der "Praktischen Winke für den musternden Arzt" für den Gebrauch der bei der amerikanisch-deutschen Kinderspeisung (Quäkerspeisung) beschäftigten Arzte (1. August, 1921). Mit sechs graphischen Darstellungen und einer Übersichtskarte. Herausgegeben vom Deutschen Zentralauschuss für die Auslandshilfe E. V. durch dessen Arztlichen Beirat. Berlin: Verlag für Politik und Wirtschaft, 1924. Pp. 80.

This brochure reports the findings in the Quaker feeding of undernourished children in Germany. Work of this kind has never been carried out on so large a scale. The funds were supplied by American Quakers, but the medical work was carried out by German physicians. This report is an amplification of a previous treatise, *Practical Hints to Examining Physicians,* which was published for the purpose of obtaining average values for the size and the weight of schoolchildren. These findings are now supplemented by similar values found in the preschool age. The results of such investigations in other countries, such as England, United States, Austria, Sweden and Denmark, are also given for the various ages.

The examinations in Germany were conducted in twenty-one large cities and in two districts. Almost a quarter of a million of children and adolescents up to the age of twenty years were examined and the averages found are given in tabular form and in graphs, making them very accessible for reference. The individuals examined were classed as normal, subnormal and hypernormal. The proper development of a child is determined by means of the semi-yearly increase in size and weight of the body. Such data have never been given much attention, especially as applying to the early years of life up to the sixth.

The examinations were made only by physicians. Only such children were selected for the feeding as showed malnutrition from insufficient food and whose malnutrition was due to changes in economic conditions. The selection was determined by the data obtained through mensuration and weighing, inspection of the body stripped down to the waist, examination of the internal organs and the past history, especially the conditions of feeding in the home and past diseases.

This report contains ninety tables, a comprehensive bibliography and an index, all of which should be of great value to physicians, school authorities, social authorities, social agencies, statisticians and municipal authorities.

TUBERCULOSIS OF BONES AND JOINTS

Tuberkulose der Knochen und Gelenke. By Prof. F. Oehlecker, M.D. 356 illustrations. Berlin und Wien: Urban & Schwarzenberg, 1924. Pp. 405.

This is an up to date text book on tuberculosis of bones and joints. In his preface the author tells us that he commenced this work before the world war and that only at this late date has he been able tc complete it. The first portion of the book deals with the pathology and etiology which is all interesting and very explicit, but offers nothing which has not been said before. Next comes the diagnosis and here the author justly states the x ray finding to be the most important modern means to obtain a definite diagnosis of localized tuberculosis in either bone or joint. Concerning tuberculin as a means to obtain a definite diagnosis in bone and joint tuberculosis the author is most skeptical, in fact he considers it of relatively little value. He says a negative von Pirquet must be considered uncertain in suspected bone tuberculosis while a definite röntgen picture would clear up any possible doubt.

The next chapter deals with the relation of traumatism to bone tuberculosis and here the author gives a pathetic picture of the many cases of bone tuberculosis found in war veterans. While he admits trauma as creating a *locus minoris resistentia,* he believes bad hygiene in improvised field hospitals, privation, underfeeding and exposures to all kinds of weather to be the underlying causes of the many cases of local tuberculosis in the young exsoldiers who had entered service in full health and strength.

Oehlecker gives credit to Bier for his method of hyperemia and also to Iselin for his method of applying the x ray in surgical tuberculosis, but without his saying so, one can read between the lines that he is not overenthusiastic about it. In speaking of heliotherapy he gives credit first to Bernhard and then to Rollier for having inaugurated this invaluable therapeutic means in its modern application. He thinks it regrettable, however, that in their works neither Bernhard nor Rollier give credit to the Greeks, the Romans and the Egyptians who were the true originators of heliotherapy. While fully appreciating the wonderful results obtained by Rollier and his disciples, this author wishes it to be understood that in the therapeutic management of tuberculosis of bones and joints he believes good substantial food, light and air and sunshine to be most important features. The utilization of sunlight at high altitudes he considers the best form of heliotherapy, but he believes that good therapeutic results can also be obtained in favorably located seacoasts and lowlands where heliotherapy may be combined with aerotherapy. Artificial light, that is to say, phototherapy, may be classed as an adjuvant at climatically unfavorable times, but its value should not be overestimated. Because the local lesion demands the same constant attention as the general treatment, he favors special sanatoria for this class of tuberculous invalids.

The second portion of this most interesting volume treats exclusively of the surgical and orthopedic management of tuberculosis of the cranium, spinal column, pelvis, hip and kneejoint, long and short bones, sternum, shoulder and elbow joints, and tuberculosis of the hand and foot. Nothing is omitted and admirable illustrations of anatomical and pathological specimens, of tuberculous deformities before and after treatment, and of orthopedic appliances and the manner of preparing them, enhance the value of the contribution. Rather interesting are the author's remarks in this chapter concerning the operation devised by our own Albee, which, as is well known, consists in the transplantation of a part of the tibia to replace the destroyed portion of the vertebræ and straighten the curvature. Oehlecker regrets that some of his German colleagues have abandoned the operation because of failures and although he too cites some of the disadvantages of the operation, he maintains that early favorable cases with not too pronounced a curvature can be greatly benefited by the Albee method, providing that the patient is kept in a recumbent position until the spinous processes are thoroughly united in the operated section.

It may safely be said that this book as a whole is one of the latest and best guides for physicians as well as surgeons in a successful management of those still so very prevalent afflictions which have their origin in the bacillus of tuberculosis.

THE HUNTERS

Memoir of William and John Hunter. By George C. Peachey. Plymouth: William Brendon and Son, Ltd., 1924. Pp. 313.

The history of those brilliant pioneers of medicine, William and John Hunter, is intimately connected with the history of Guy's Hospital. So it is fit that Peachey write this work concerned with the labors of the two Hunters. There are many reasons why physicians, no matter in what field of medical endeavor, should read this book. Primarily, as a debt to themselves and indirectly to the profession they represent. No more thrilling story of human accomplishment can be imagined. We too soon forget our heroes of medicine, heroes in the work of construction, for the welfare of man, while the military heroes, who specialize in destruction, find many morbid followers. Assurance is given that the physician who reads this book will pay his obligations gladly for he will be repaid many times in the reading.

Anatomy, yes medicine as a whole, owes a debt of gratitude to these two men, the Hunters. The least we can do is to better know them. They have inspired many followers; may this work serve to broaden the circle of their admirers.

KALEIDOSCOPE

Arnold Waterlow. A Life. By May Sinclair. New York: The Macmillan Company, 1924.

Turn the tube of this toy fantasy and patterns tumble into gleaming form. Another turn and they shift and reform, stars and triangles, crystal designs, color and no color. Lives tumble themselves into such ever shifting pictures. And within the sharp fragments of each life lie color and grey routine.

A play of triangles is Miss Sinclair's latest book. Arnold Waterlow is impelled into triangular situations from the moment of birth. Arnold, his mother, and Richard, his older brother; Arnold, his mother, and the dead child; good boy, bad boy, and father; Arnold, his mother and his father. Always Arnold's corner of the triangle is the one that gives. He learns in infancy that the exquisite torment of his love for his mother finds assuagement only through suffering. A tragic lesson for a child, but one only too frequently learned.

The rest of his life Arnold continues this piecing together of different triangles. Mother—son—wife; mother—son—mistress; to say nothing of son—wife—and lover, and son—wife—and mistress! The patterns shift into each other with their perpetual gleam of suffering, the sharp gash of a ragged triangle. At this technical job, Miss Sinclair has surpassed herself. Naturally the only straw Arnold Waterlow has to cling to is his philosophy. It becomes a trifle monotonous. And finally even the philosophy suffers what appears to the skeptical reader as a setback. Arnold has shaken himself free of his mother at last, he is in sight of the way out of the treadmill that his life has become. Then comes the crash—and after he has weathered it, there is nothing left but to seek the mother tenderness of his wife. She at least gives him what in his childhood his own mother denied. And he is safe on familiar ground.

When Miss Sinclair makes her characters try to mould things closer to their hearts' desires, one has an uneasy feeling as though Miss Sinclair were grimly saying: "It can't be done—really." Sad, but true. And the romance of every life is in this shattering of oneself against supposedly beneficient Fate. While the irony ready to the hand of writers like Miss Sinclair is that intrepid people still keep on disbelieving and trying. In spite of everything she has said and will say!

Medicoliterary Notes.

Recent publications of interest are *Race Hygiene and Heredity,* by Hermann W. Siemens, translated by Dr. Lewellys F. Barker (Appleton), and *Rimbaud, the Boy and the Poet,* by Edgell Rickword (Knopf).

More than one fourth of all negro children born alive die before five years of age, according to Dr. J. H. Mason Knox, writing in the *Journal of the American Medical Association.* Among the outstanding causes of infant mortality in negro infants are: prematurity, tuberculosis, syphilis and secondary pneumonia. In the registration area deaths from syphilis and tuberculosis are each four times as frequent in the negro as in the white, and from pneumonia 2.3 times as many. The three diseases—syphilis, tuberculosis, and pneumonia—account for twenty-nine per cent. of all infant deaths among negro children, and only seven per cent. among white children.

Announcement has recently been made that the American Council of Learned Societies will produce a dictionary of American biography on the plan of the well known *British Dictionary of National Biography.* Dr. J. Franklin Jameson, chairman of the committee of management, is director of the Department of Historical Research in the Carnegie Institution, Washington, and was chairman of the committee from the American Council of Learned Societies that drew up the original plan for the work. At least ten years will be spent in compiling the dictionary, which will include sketches of the lives of about twenty thousand illustrious Americans.

* * *

The following quotation from a number of the *Virginia Health Bulletin* needs no explanation as a commentary on the evils of red tape:

The nurse visited a school. The teacher pointed out a child who had enlarged tonsils. The nurse, having given the inspection, and feeling that it was an urgent case, started directly to the child's home, a distance of two miles. The parents were found to be cooperative, but the nurse learned that there was no family physician, only one the mother had had for herself about a year before in an emergency. The nurse drove ten miles to see the physician to ask him to make the diagnosis. She then drove back the ten miles, got the child, and took him to the doctor, another ten miles of driving. By the time the dagnosis had been made, the child returned home, and the nurse back to headquarters, fifty miles had been driven. An operation having been advised, the surgeon had to be seen and bargained with. He was twenty miles away; it was another twenty miles to get back to the home and instruct the mother as to the preparations of the child before the operation. Then forty miles were covered in taking the child to the hospital and the nurse back to headquarters. Eighty miles were driven that day and forty the next day in bringing the patient back home.

An interesting document recently published in France is the account of the trial and execution of the notorious "modern Bluebeard," Landru, as seen by the three chief reporters who covered the case—Henri Béraud, Emmanuel Bourcier, and André Salmon, all of whom have written novels. There are included interesting pen portraits, not only of the gay little engineer with his bald head and great beard who is said to have had 293 mistresses, but also of the prosecuting attorney, M. Godefrey, and the defense attorney, M. de Moro-Giafferi, a kind of Parisian Clarence Darrow.

Abstracts from Current Literature

GASTROENTEROLOGY

Pathology and Symptoms of Duodenal Ulcer.—H. Tyrrell Gray (*British Medical Journal,* June 14, 1924) states that the predisposition to duodenal ulcer is the relative increase of the normal vagus stimulation, which establishes the socalled duodenal stomach. Tobacco is the outstanding cause. Factors which may excite ulceration in such a type of stomach are: 1, acid; 2, distention; 3, trauma; 4, infection, and possibly 5, alcohol; the effect of all these in producing ulceration is accentuated by an incompetent pylorus. Any combination of these exciting factors may determine ulcer formation in such a type of stomach; but in the sympathetic type with the closed pylorus (the antithesis) a gastric ulcer is the more probable result.

Penetrating Ulcers of the Stomach.—John L. Kantor (*Medical Clinics of North America,* July, 1924) states that penetrating ulcers of the stomach may clinically and röntgenographically resemble cancers. A differentiation between the two may be made by observing the effect of bedrest on the size of the niche. The seven patients treated conservatively by the author showed disappearance of the niche and became well, although it is not implied that they will remain well. Medical treatment is the method of choice. A properly managed cure implies absolute rest in bed for from one month to six weeks. No form of treatment yet devised seems to affect the tendency to recurrence which is presumably due to some unknown constitutional factor of diathesis.

Röntgen Ray Studies of Stomach Function.—Julian L. Rogatz (*American Journal of Diseases of Children,* July, 1924) found that the infant stomach exhibits a socalled peristaltic function, the actual existence of which may be demonstrated by röntgenographic exposures. The infant stomach reacts differently to fluids and to semisolids, as follows: a, with fluids the stomach assumes either a pear or oval shape, horizontal in position and extending to or beyond the midline, the air bubble being large or moderate in size; b, with foods of very thick consistency the baby's gastric organ contracts down to a small, circular or oval shape, barely reaching the midline, never extending beyond, and with a very small air bubble, or often none at all. The peristaltic reflex has an important, practical significance in the treatment of pylorospasm and habitual vomiting.

Value of Feeding During Operations on the Stomach.—Herbert H. Brown (*British Medical Journal,* April 26, 1924) avoids postoperative shock and leaves the patient in a better condition after operation than before it by using the following procedure: Before the inner row of catgut sutures surrounding the gastrojejunostomy opening is quite completed the suturing is stopped, leaving an opening of about a quarter of an inch or less. The jejunal clamp is removed, and stomach and jejunum compressed between the finger and thumb of the left hand to prevent escape of fluid; a No. 10 soft rubber catheter, connected by a short length of tubing to a funnel, is introduced through the opening and passed along the jejunum (the finger and thumb keeping up compression around it), until about eight inches or more have passed along the gut into a coil which is within the abdominal cavity. The food, consisting of a pint of peptonized milk with a beaten egg and one ounce of brandy, is then poured slowly into the funnel through a gauze strainer. The catheter is then withdrawn and the operation is completed.

Acute Appendicitis in Children.—W. A. Thompson (*British Journal of Children's Diseases,* July-September, 1924) states that the diagnosis is comparatively difficult because of the difficulty of obtaining an accurate history and a proper physical examination. The symptoms of appendicitis progress much along the lines followed in the adult, but the early pain may easily be overlooked. It is usually umbilical or diffused throughout the abdomen at first, and later may be located in the right iliac fossa, right lumbar region, suprapubic region, or it may remain umbilical. Vomiting is the next feature. It is usually present in every case and in the majority occurs immediately after the pain. Localized tenderness next appears and is the most important evidence of all. It gives an indication of the position of the appendix. The temperature is not of much clinical value in the child. The differential diagnosis includes pyelitis, acidosis, inflamed glands in the ileocecal region, basal pneumonia and diaphragmatic pleurisy and Henoch's purpura. A drainage tube is inserted in all cases of perforation and in cases where there is much oozing from previous adhesions. The tube is removed as soon as possible after thirty-six hours. Eserine or pituitrin, in some cases both, are used from the third day to promote evacuation and relieve or prevent flatulence.

Chronic Primary Intussusception in Children.—H. E. Marsh (*Annals of Surgery,* February, 1924) offers the following conclusions: Chronic primary intussusception in young children is relatively uncommon. The clinical and operative histories of two children operated on at the Mayo Clinic are recorded. The symptoms may be vague and misleading, but careful investigation into the past history, and observation of the child during an attack, will often suggest the true condition. Intermittent attacks of abdominal pain of sudden onset, occurring over a period of weeks or months, of short duration, and disappearing suddenly with complete relief, are characteristic.

Symptoms of Achylia Gastrica.—Bryce W. Fontaine (*Southern Medical Journal,* July, 1924) says that the diagnosis of achylia gastrica cannot be made from the history, from a study of the symptoms, or from a radiographic study, but is absolutely dependent upon an analysis of the gastric contents after a suitable test meal, and it will frequently be overlooked unless this analysis is made a routine part of every general examination.

The Creatinin Test for Renal Function.—Ralph H. Major (*Southern Medical Journal,* July, 1924) says that the principle underlying the creatinin test is the calculation of the creatinin excretion for definite periods of time before and after the injection of creatinin into the circulation. In most of the tests the following procedure has been carried out: The patient empties the bladder and the urine is collected for the period of one hour. He then is given 0.5 grams of creatinin intravenously, the urine is collected for one hour and then again at the end of two hours. The excretion of creatinin for the first hour and for the second hour after injection is compared with the excretion before injection.

Partial Duodenal Obstruction.—George E. Nesbit (*Irish Journal of Medical Science,* April, 1924) says that partial duodenal obstruction can be demonstrated in a large proportion of cases with chronic dyspeptic symptoms. The cause of the obstruction varies, but the most common is compression by the superior mesenteric artery. It is nearly always associated with an abnormal condition of the colon. The possession of a mesentery, i.e., mobility, alone is not sufficient; some other factor is necessary, such as descent over the pelvic brim, chronic constipation, or loss of tone in the abdominal muscles. Treatment consists in regular emptying of the colon with support for the latter by an efficient abdominal belt. Failing improvement on these lines, colopexy is indicated, or possibly duodenojejunostomy.

Unsuspected Hypertoxic Appendicitis.—E. St. Jacques (*Canadian Practitioner,* July, 1924) emphasizes the following points.

1. Acute appendicitis is sometimes hypertoxic and rapidly gangrenous. 2. The toxicity induces acute infectious enteritis immediately. 3. Diarrhea seems the dominant characteristic of these cases. 4. Pain is present; at the onset localized at McBurney's region—as a very careful inquiry brings out—but is rapidly generalized to the whole of the abdomen on account of the acute enteritis. 5. The degree of pain is moderate at McBurney's point at the onset, usually escaping the attention of the patient on account of its spreading rapidly to the whole abdomen. This is due to the enteritis. 6. Of muscular defence or rigidity there is none or little at the onset, but is well marked when diffuse peritonitis sets in. 7. The pulse is usually very rapid from the start due to the very infectious character of the disease. 8. The temperature may be only moderate and is sometimes subnormal. 9. The general condition of the patient is decidedly bad from the onset. 10. Let us not forget that this

particular variety of acute hypertoxic appendicitis is not rarely met with in children, as Comby and Dieulafoy have well pointed out, in their clinical lectures, and also in adults, and that its course is rapidly fatal, if not operated upon early. 11. The etiological factor is the colon bacillus not infrequently, streptococcus frequently and, in the rapidly hypertoxic variety, anaerobic bacilli, the Welch's bacillus, or other. 12. Lastly, never lose sight of the clinical fact that in children, so prone to pneumococcic peritonitis—which is usually primitive without a former acute pneumococcic infection—this type of appendicular peritonitis is in the vast majority of cases accompanied at the very onset by diarrhea.

Drainage of the Peritoneal Cavity and the Physiological Protective Capacity of the Peritoneum.—As a result of his experiments on animals, L. Schönbauer (*Wiener klinische Wochenschrift,* April 24, 1924) comes to the conclusion that drainage has no unfavorable influence upon the resorptive powers of the peritoneum, but it cannot draw off the secretions. Drainage is indicated in cases in which the source of the infection cannot be closed off and where a clean condition of the wound cannot be achieved. It should be used for the purpose of walling off sections of the peritoneum that have not as yet been infected. The peritoneal cavity may be closed after operations only when the peritoneal exudate is sterile.

Partial Gastrectomy for Gastrojejunal Ulcer.—D. C. Balfour (*Annals of Surgery,* March, 1924) gives a detailed and illustrated account of the operation herein outlined, stating that it has been highly successful at the Mayo Clinic.

The operation consists in cutting off the gastroenterostomy, excision of the lesion, closing the opening in the jejunum, resecting the pyloric end of the stomach, including the opening of the anastomosis, with restoration of continuity by whatever method is best suited to the case. This operation, partial gastrectomy, has such distinct advantages, particularly in its end results, that I bring it to your attention.

Hemorrhage in Abdominal Injuries.—J. M. Mason (*Annals of Surgery,* March, 1924) gives several statistical tables of hemorrhage series, from the point of view of mortality per cent., and concludes as follows: To secure a reduction in the mortality rate of the small hemorrhage series, which stands at thirty-six and one tenth per cent. where there is visceral injury, we must depend upon early operation; refinement of surgical technic; lessening the shock of prolonged ether anesthesia by a more extensive use of local anesthesia, nitrous oxide or ethylene anesthesia, and the most careful attention to the details of after treatment. To secure a reduction in the mortality of the large hemorrhage series, which stands at eighty-seven and two tenths per cent. in the operative cases, all the requirements above noted must be observed, and donors for transfusion must be obtained regardless of trouble or expense.

Chronic Appendicitis.—J. Selinger (*American Journal of Surgery,* March, 1924) reviews the symptoms of this disease, and its peculiar aptitude for being confounded with other abdominal affections. He points out the differences of chronic appendicitis from some of these, and stresses the value of a clear, complete, and concise history in making the differential diagnosis. He concludes: "Chronic appendicitis is not a mental condition. It is truly a pathological process, a symptom producing disease. It requires study, a differential diagnosis and treatment. This treatment is surgical. It is not an emergency operation, but the organ should be removed at convenient time, soon after the diagnosis is made. The close lymphatic association between the appendix, the gallbladder and the stomach should be a warning of the probability of disease of the two latter organs, if a diseased appendix is allowed to remain."

Treatment of Severe Gastric and Duodenal Hemorrhage.—Arthur F. Hurst (*Lancet,* May 31, 1924) recommends the following treatment in cases of severe gastric and duodenal hemorrhage: A stomach tube is passed just far enough for the end to reach beyond the cardia to prevent direct disturbance of the bleeding surface. The stomach is then emptied with an evacuator. The stomach is next washed out with about four ounces of ice cold water, and this is repeated until the washings are no longer blood stained. An iced one in one thousand ferric chloride solution may be used instead of water. When the last traces of water have been evacuated, a dram of one in one thousand adrenalin chloride solution is poured into the stomach before withdrawing the tube. The gastric juice should be rendered inactive by neutralizing it with alkalies, like oxide of magnesia, calcium carbonate, calcium chloride, or bismuth carbonate. All septic foci should be sought and carefully eradicated. Preparations should also be made for transfusion if necessary. The only indication for operation in the acute stage is the occurrence of severe and persistent hemorrhage in an elderly individual with a long history of chronic ulcer and degenerated arteries.

Gastrojejunocolic Fistula.—W. A. Brams and K. A. Meyer (*Surgery, Gynecology and Obstetrics,* May, 1924) offer the following résumé to their series of cases:

1. Gastrocolic and gastrojejunocolic fistula have increased in frequency because of the more common surgical treatment of gastric and duodenal ulcers. 2. The prefistulous stage is the gastrojejunal ulcer after operation. 3. Any or all of the manifestations of fistula may be absent, but persistent dyspepsia and diarrhea after operation should lead us to suspect a gastrocolic or gastrojejunocolic fistula. X rays in several positions repeated several times, as well as the various methods of introducing colored substances per rectum and recovering them on washing out the stomach may establish the diagnosis in doubtful cases. 4. The four cardinal symptoms of a welldeveloped case of fistula are fecal vomiting, fatty stools, diarrhea, and the x ray findings. 5. Radical surgical treatment is the only method of curing the condition, and the earlier it is undertaken the easier will be the operation and the shorter the postoperative course.

Treatment of Hypertrophic Pyloric Stenosis.—F. John Poynton, T. Twistington Higgins, and J. M. Brydson (*Lancet,* February 2, 1924) advise operation at the earliest possible moment after the diagnosis has been definitely established. In the present state of our knowledge of the pathology of pyloric stenosis, operation offers the most speedy and certain cure of the disease. The Rammstedt procedure is the operation of choice. The best results are obtained with the earliest possible operation. The only absolute diagnostic sign is the presence of the pyloric tumor; without this sign operation is justified only in rare instances. In breast fed infants, where symptoms and signs develop suggestive of pyloric stenosis, the infant should not be weaned until a definite or negative diagnosis can be made, because experience has shown that feeding with breast milk is of great assistance to recovery.

Transverse Incision in Appendicitis.—A. E. Rockey (*Annals of Surgery,* May, 1924) describes the operation in detail, gives positions, and discusses his system of dependent drainage. In the operation the fibres of the transversalis and internal oblique muscles are directly transverse to the line of incision. The internal oblique, though varying a few degrees, is further cut, and so soft that the variation is of no consequence in operation. The actual cutting is confined to the fascia of the rectus and the aponeuroses of the muscles. The incision is then spread wide by a vertical, or up and down pull. The wound is drained through the lowest part of the cavity, i.e. the outer end of a transverse incision.

The author states that hernia is very rare after operation by this method, and he vehemently recommends it and the dependent drainage in the worst of suppurative cases, saying that its superiority in these will soon demonstrate its special fitness for the majority of others, until its general use will become a routine.

Physical Treatments in Gastrointestinal Disorders.—Anthony Rassler (*American Journal of Eelectrotherapeutics and Radiology,* May, 1924) emphasizes the fact that the d'Arsonval current has been of help in hypertension cases, not a few patients having felt better after the treatment, and, although the drop in the mercury column has been definite, many have reported that it does not last. He believes that the best results associated with the d'Arsonval treatment are obtained by placing the patient on a low diet, the employment of radium, hot packs, rest in bed, freedom from emotional disturbances, with small doses of the iodides and the maintenance of brisk elimination. He emphasizes the value of diathermy in the treatment of painful gallbladder conditions, with the relief of subjective and objective pain in this way. He refers to the employment of the x ray in the treatment of hyperthyroidism, stating that it has become recognized as a valuable method of treatment. He prefers the x ray to radium in the treatment of fibroma. He speaks of the value of the x ray in hyperchlohydria.

Vitamines and the Borderland Between Health and Disease.—W. Cramer (*Lancet*, March 29, 1924) believes that there is a misconception of the mode of action of the vitamines, which has led to an underestimation of their value in nutrition. The borderland between health and disease, due to a deficiency of the vitamines, has not been sufficiently explored. Animal experiments show that highly differentiated organisms require a maximum supply of vitamines, especially in the early part of their life, to reach their full development. Any deficiency in this supply leads to imperfect development, which need not necessarily produce disease or poor health and need not affect reproduction. The result of such a deficiency is evinced in an undersized, poorly nourished population with a diminished resistance to disease. Vitamines have a positive physiological action, similar to that of the hormones. Specific pathological lesions can be demonstrated when vitamines are deficient in the food. The greatest need for these hormones is felt immediately after birth and in the early years of life at the time when the organism is adapting itself to its new surroundings and when the tissues assume their respective functions. This conception may be extended even to other than deficiency diseases.

Etiology of Anaphylactic Phenomena.—As a result of his observations, Karl Hajós (*Wiener klinische Wochenschrift*, June 12, 1924) comes to the conclusion that the most important factor in alimentary hypersensitiveness is a constitutionally deficient gastrointestinal mucosa or a tendency toward dyspepsia, enteritis, etc., inasmuch as the penetration of unchanged proteins would be difficult to explain in any other way. The rectal source of urticaria in one of his patients and the attack of asthma in another show that a circumvention of the liver results in a greater predisposition to the anaphylactic attack in some instances. Therapeutically, animal charcoal gives some very good results in cases of alimentary anaphylaxis, especially in urticaria. The effect of Witte peptone, given by mouth, appears to be problematical in many cases, as the oral administration of the peptone only acts as a desensitizer when it reaches the blood stream in an unchanged condition. In the nonspecific process of desensitization only the parenteral route deserves consideration. The active immunization is possible with fluid protein extracts and the omission of the offending article of food from the diet is often very difficult and bothersome to the patient without the promise of achieving success.

Treatment of Hour Glass Stomach.—C. L. Gibson (*Annals of Surgery*, November, 1923) says that in general it may be stated that resection in the hour glass stomach is to be avoided if the condition can be adequately dealt with otherwise, for the following reasons:

1. The hour glass stomach is the end result of a long standing, particularly severe gastric ulceration and most of the patients are greatly debilitated and poor risks.
2. Any form of resection has a definite risk of being followed by any of the varieties of pneumonia.
3. Gastroenterostomy may very often be performed with great ease under local anesthesia, particularly if the abdominal wall is thin and lax and the stomach is large, or ptosed, as it generally is in emaciated patients.
4. Other operations of less severity give good results.

In conclusion I would call attention to the hint furnished by the size of the lower pouch, as regards the presence of a second obstruction at the pylorus, and it is in these cases where the stomach is divided into pouches of different sizes, or the lower pouch is distinctly large, that the operation of double posterior gastroenterostomy is particularly indicated.

Lymphaticostomy in Intestinal Obstruction.—W. A. Costain (*Surgery, Gynecology and Obstetrics*, February, 1924) describes the experiments which led him to the following conclusions:

1. Toxemia in acute intestinal obstruction is due to the absorption of toxins formed from necrotic tissue.
2. When in total occlusion the upper obstruction is just below the pancreatic ducts there is rapid necrosis of tissue above the obstruction and death, but when the obstruction occurs above the ducts just beyond the pylorus even though more area is obstructed the accessory gland digestive juices, and especially that from the pancreas, are neutralized lower down and necrosis and death are considerably delayed.
3. The absorption of toxins is through the lymphatics to the thoracic duct.

The practical application of these findings to surgery has not been worked out. Merely touching on their bearing on surgery one may say that they call for the withholding of fluids by mouth, dehydration being combated by intravenous infusions. They indicate that in all operative procedures the lymphatics should be taken into account, and to prevent a continuation of the absorption of toxins in some obstructions it may be necessary to supplement the relief of the obstruction by a lymphaticostomy. Should this be done the continual administration of water through a duodenal tube will help to keep a constant drainage from the duct and prevent blocking.

Multiple Polyposis of Gastrointestinal Tract.—A. E. Struthers (*Surgery, Gynecology and Obstetrics*, May, 1924) presents the following conclusions:

1. Multiple polyposis of the intestinal tract is a serious disease from the standpoint of morbidity and mortality. 2. The cause of intestinal polyposis is not known, although chronic ulcerative colitis appears to be a prominent factor. 3. There is no specific medical treatment, and operation undoubtedly offers the best results in all cases. 4. The predominant symptoms are diarrhea, with the passage of pus and blood, vague abdominal pain, and rectal tenesmus. 5. Multiple polyposis is a disease of the large intestines and of the stomach. The small intestines are rarely involved. 6. Proctoscopic examination should be made routinely in all cases of dysentery of more than a few days' duration. 7. The röntgen ray is practically the only means of diagnosing multiple polyposis of the stomach, or above reach of the proctoscope in the bowel. 8. The disease terminates in malignancy in a large percentage of cases. 9. Most marked involvement of the colon is found in the cases which begin as a mild diarrhea and later become chronic. 10. The findings in one patient would tend to confirm the correctness of Menetrier's terminology "gastritis polyposis."

Isolation of Submucosa in Intestinal Anastomosis.—A. J. Graham (*Surgery, Gynecology and Obstetrics*, February, 1924) offers the following conclusions from his study:

1. In Lembert's time the principle was established that "raw tissues of like nature will unite if held approximated long enough" and union was secured by approximating the peritoneal coats.
2. Halsted showed that all intestinal suturing must be with the submucosa as the basis (the skeleton).
3. Students should see this structure isolated; they take better stitches afterward.
4. The submucosa must be taken into consideration in regard to drainage of bacteria and toxins from obstructed loops of bowel; and in regard to making and closing fistulae. It may be utilized to prevent extension of peritonitis by walling off areas.
5. All through and through and most Lembert stitches slough to the lumen of the bowel; a few encyst at the serosa, being cut off by the action of the muscular coats.
6. The tendency to throw off a foreign body by sloughing out is stronger than the tendency to absorb it.
7. Visceral union is a matter of sloughing of suture material, and of absorbing superfluous tissue, and is accomplished in a few days.
8. From the study of this tissue there has been evolved the aseptic resection of bowel by Halsted and others.

Studies in Pancreatic Function.—C. W. McClure (*American Journal of Medical Sciences*, May, 1924) presents the following conclusions:

1. Normal enzymic concentrations of duodenal contents have been established for the methods and procedures described for estimating enzymic concentrations in duodenal contents obtained by the use of the procedures described.
2. Abnormalities in enzymic concentrations having been found only in the presence of some lesion involving the pancreas, either primarily or secondarily, it is concluded that the estimation of enzymic concentrations of duodenal contents furnishes an index to the activity of the external secretory function of the pancreas.
3. The findings in normal persons indicate that the essential factors in stimulating the secretion of pancreatic juice are the products of digestion rather than the acidity of the gastric chyme.
4. The time coincidence of the onset of the flow of bile and pancreatic juice suggests a common stimulant.

5. The external secretory function of the pancreas, as measured by the enzymic concentration of duodenal contents, was found to be much depressed below the normal in chronic pancreatitis.

6. Acute pancreatic necrosis, cancer of the head of the pancreas, and lesions obstructing the pancreatic duct were accompanied by marked abnormalities in the enzymic concentrations of duodenal contents. Obstructive lesions caused great diminution, while acute necrosis often caused dissociation of the concentration of the enzymes.

7. In obstructive jaundice estimation of enzymic concentration of duodenal contents is of aid in localizing the site of the lesion, and in the differential diagnosis between its benign malignant character.

Alimentary Asthma.—Ludwig Hofbauer (*Wiener klinische Wochenschrift,* March 29, 1923) states that the attempt to trace bronchial asthma to anaphylactic phenomena, which are produced by the ingestion of certain foodstuffs, and the consequent desensitization by proteins produced by these substances as a result of cutaneous inoculations, are not applicable in every case. He recommends for these refractory cases the use of humming exercises, in which the patient practises abdominal breathing, which act as massage of the intestines, thereby preventing intestinal putrefaction, which may be a cause of the attacks.

Senile Atrophy of the Liver. — Isolde T. Zeckwer (*Journal of Laboratory and Clinical Medicine,* April, 1924) tabulated the liver weights in consecutive autopsies according to age, excluding, however, gross lesions of the liver, aside from senile atrophy, which would materially alter the weight, such as cirrhosis, tumors, amyloid change, and abscess, and omitting cases under twenty years of age. The study included 309 males and 375 females. A chart is given showing the average weights of livers grouped in five year periods. The greatest average weight was attained between thirty-five and forty years, and was 1704 gm., after which there was a steady decline in weight to an average of 1054 gm. in individuals over 85 years old. A second chart shows the average weights of livers in the two sexes at different ages. The average weight in males is uniformly greater than in females, but the two curves run parallel, both reaching the maximum of 1773 gm. in males and 1612 gm. in females in the third decade, and progressively declining to 1174 gm. in males and 1020 gm. in females after eighty years of age.

Duodenal Hernia a Misnomer.—E. Andrews (*Surgery, Gynecology and Obstetrics,* December, 1923) reports a case which he compares to several in literature, and explains on his own theory and conclusion that duodenal hernia is a congenital anomaly due to imprisonment of the small intestine beneath the mesentery of the developing colon.

ANESTHESIA

Acetylene Anesthesia.—Amiot and Hermet (*Bulletin médical,* August 27 and 30, 1924) note that chemically pure acetylene is a gas with a penetrating odor, but free of the garliclike odor of acetylene made from calcium carbide. As it is extremely inflammable and dangerously explosive when mixed with air or oxygen in sufficient proportions, no flame should be allowed in the vicinity of the patient. The anesthetic properties of acetylene vary in different animals according to the activity of their oxidative processes. Birds, which consume much oxygen, are very sensitive to it, mammals less so, fish hardly at all, and worms and anaërobic organisms not all. Acetylene is a more active anesthetic than nitrous oxide and even ethylene. It is definitely anesthetic when mixed with ten to thirty per cent. of oxygen, which is not true of nitrous oxide. The medullary functions seem to be spared much longer than they are by ether, chloroform or ethyl chloride. Any nitrous oxide apparatus will serve likewise for the prosecution of acetylene anesthesia, but care must be taken not to mix acetylene and oxygen under pressure. The gas is given about like nitrous oxide, but with a larger ratio of oxygen. Cyanosis, rapid breathing and muscular rigidity call for an immediate increase of the oxygen allowance. Analgesia supervenes very quickly, sometimes in thirty seconds. This is an excellent property of acetylene for brief anesthesias, as the drug entails far less risk than ethyl chloride. Muscular resolution and sufficient quiet in the abdominal cavity are obtained in six to eight minutes. The margin of safety is greater than with nitrous oxide. The condition of the reflexes is of no great significance; a lively palpebral reflex may be present in perfect surgical anesthesia. Care should be taken, however, not to allow an exaggerated degree of pupillary dilation. If the anesthesia is prolonged, the oxygen admixture can be raised to as high as 50 per cent. A preliminary injection of scopolamine or atropine will obviate the otherwise very copious salivation. Marked trismus sometimes occurs even during satisfactory resolution. From the standpoint of the surgeon, acetylene is generally more satisfactory than nitrous oxide. Many abdominal operations can be carried out as easily as with ether, and in none of the authors' cases was it necessary to use another anesthetic. There is frequently, if not always, a hypertensor effect, but this did not seem to increase hemorrhage, as it often does in the case of nitrous oxide. Recovery from the anesthesia is rapid, never exceeding three or four minutes. Vomiting was rather frequent, but seldom persistent.

Anesthetic Records.—J. S. Lundy (*American Journal of Surgery,* January, 1924) reproduces numerous records and offers various observations upon them, summing them up as follows.

1. Record keeping will be the future forte of those anesthetists and surgeons who will be satisfied with nothing but the safest surgical procedures.
2. Stimulants in spinal anesthesia shorten the danger period.
3. Nitrous oxide oxygen may be administered to the very old and the very young when great care in the administration of the anesthetic is exercised.
4. That anesthetic records are not difficult to keep and that future advances in practical anesthesia will keep pace with the popularity of such record keeping.

Local Anesthesia in Neck Operations.—W. R. Meeker and H. W. Hundling (*Surgery, Gynecology, and Obstetrics,* June, 1924), say that the neck is one of the most favorable regions of the body for performing operations under local anesthesia. The anatomy of this region is such that either infiltration or regional methods (nerve block and field block) may be employed. If anesthesia sufficient for the conclusion of the operation is to be induced as a preoperative procedure, regional methods are more frequently employed because of the deeper anesthesia. Block of the cervical plexus by the posterior route is employed in cervical laminectomy as part of the procedure in craniotomy for cerebellar explorations, and occasionally when there are contraindications to the employment of the lateral routes. Of the two lateral routes the oblique is preferable because of the greater anatomical safety. Block of the cervical plexus by the lateral oblique method is valuable, either alone or combined with infiltration, in operations on the lateral and anterior regions of the neck. Operations which may be satisfactorily performed under local anesthesia include thyroidectomy, laryngectomy, thyrotomy, and removal of tumors, excision of esophageal diverticula, removal of lymphatic glands, excision of branchial cysts, tracheotomy, ligation of thyroid or carotid vessels and cervical laminectomy. For the excision of furuncles and carbuncles, extensive degenerating glands of the neck and widely disseminated carcinomatous glands, general anesthesia methods should be employed.

Urological Surgery Under Sacral Anesthesia.—O. S. Lowsley (*Surgery, Gynecology and Obstetries,* November, 1923) reports on a series of six cases. He says that the series is much too small to draw general conclusions. His observations and the experiences of others lead him, however, to believe that sacral combined with parasacral is the anesthesia of choice in performing major urological operations *per perineum,* particularly prostatectomy. In perineal prostatectomy under this type of anesthesia there is less bleeding and less shock than there is with any inhalation anesthesia.

Reflex Rigidity Under General Anesthesia.—A. E. Guedel and K. R. Ruddell (*American Journal of Surgery,* April, 1924), say that, contrary to general opinion, the peritoneum is an organ of such low sensibility that it does not in any way produce an interfering reflex response during the course of an operation. The greatest operative reflex interference comes from stretching the muscles alone. In local infiltration of the abdomen as a rigidity corrective measure, only the muscle need be infiltrated.

Medicolegal Notes.

KENTUCKY STATUTE AUTHORIZES ISSUE OF PRESCRIPTIONS OF LIQUORS FOR MEDICINAL PURPOSES

The Kentucky Court of Appeals holds, Commonwealth v. Galloway, 261 S. W. 887, that Acts Ky. 1922, c. 33, §32, providing that "Physicians may issue and pharmacists may fill prescriptions for intoxicating liquors, under the restrictions of the national federal law," contemplates the issue of prescriptions for liquors by physicians for medicinal purposes, and as the mere permissive right to issue them under the restrictions of the federal act cannot be construed as an inhibition against their issue in any other way, no such duty is imposed by the State act.

The act is a penal one, and the court refused to read into it by reference an intention to create an offense and fix a penalty therefor when the language used is only the granting of permission to do a thing in a particular way without prohibiting the dong of that thing in any other way.

"IMMEDIATE SURGICAL RELIEF" DEFINED.

A rider in an employers' liability policy provided that the policy should not cover "such immediate surgical relief as is imperative," which the policy itself had expressly covered. The Arkansas Supreme Court holds, United States Casualty Co. v. Johnson Drilling Co., 255 S. W. 890, that the words quoted contemplate emergency relief—such as must be given instantly or immediately following the accident to prevent impending death or to assuage or prevent suffering. "These words have no reference to such surgical and medical treatment and hospital charges and compensation for nurses and such other expenses as are incident to, and necessarily incurred in, the usual and ordinary treatment of the victim of the accident some time after the accident occurred and which are continued in order to restore him, if possible, to his normal condition, and by so doing to lessen the damages for which the person causing the injury would be liable."

WAS DEATH FROM FALL RESULT OF ACCIDENT OR DISEASE?

In an action on a policy insuring against injury by "accidental means," the Texas Court of Civil Appeals holds, Aetna Life Ins. Co. vs. Robinson, 262 S. W. 118, that if the insured slipped and fell upon the pavement, inflicting the injuries from which he died, his death would have been caused by "accidental means;" but if, because of a fainting spell, or some other bodily infirmity, he was caused to fall, thereby inflicting the injury, though the injury may have been the sole cause of his death, it would not necessarily follow that the death was occasioned by accidental means. If such an injury would naturally follow from a fall occasioned by a fainting spell or other bodily injury, not accidental in its nature, then the death would not be accidental within the meaning of the policy.

Where the evidence of expert physicians raised the issue that the insured's death might have resulted from apoplexy, it was held error to refuse to submit to the jury the issue whether apoplexy caused or contributed directly to the death.

EMPLOYER'S LIABILITY WHERE EMPLOYEE CHANGES HOSPITALS

The Illinois Supreme Court holds, Old Ben Coal Corp. v. Industrial Commission, 311 Ill. 35; 142 N. E. 507, that, while the rule in that state is that the employer has a right to prescribe where the medical attention and hospital services shall be procured so long as they are such as are reasonably necessary and adapted to the purpose of treating the injured employee, yet the employer does not, because the employee goes to another hospital, and thereafter demands medical and hospital services, avoids liability for such services without tendering other services of that character to him.

The fact that, as an emergency, the employer had the employee taken to a certain hospital, from which he was the next day taken by his family, does not, it is held, in the absence of competent service of that character after demand, relieve the employer from liability for such service.

EMPLOYER'S AGREEMENT FOR CONSIDERATION TO FURNISH MEDICAL TREATMENT TO EMPLOYEE NOT AFFECTED BY COMPENSATION ACT

Where an employer, though he has subscribed to the workmen's compensation fund and has complied with the law in relation thereto, agrees with an employee, in consideration of deductions from the latter's wages, to furnish the employee competent and skilled medical treatment for illness or injuries suffered in his service the West Virginia Supreme Court of Appeals holds, Ashby v. Davis Coal & Coke Co., 121 S. E. 174, that he is bound to maintain for that purpose a competent and skilled physician, notwithstanding the provisions of section 22 of the West Virginia Workmen's Compensation Law. Where the employer neglects to perform the duties so imposed and by reason of such neglect the employee is injured, such employer is liable in damages to the employee to the same extent that the physician would be were he sued for the injury.

CONTROL OF WARD IN MUNICIPAL HOSPITAL UNDER CITY CHARTER

In mandamus proceedings on the relation of the University of Cincinnati against the Director of Public Safety of the city, to require the defendant to cause to be made at the expense of the relators the equipment of ward C-3 for the purpose of surgical research, the defendant maintained that the power of setting aside a ward for surgical research or other hospital purposes rested in him as an official of the city, and was not vested in the directors of the University. The question was, since there could be no dual incompatible control of the matter, in whose hands was lodged the power of setting aside such a ward.

The Ohio Supreme Court held, State vs. Tudor, 143 N. E. 669, that under the city charter, V 1, 2, the administrative and executive control of municipal hospitals is still lodged in the director of public safety, while the medical work, teaching and nursing have been placed under the control of the university directors, and that the directors could not, by mandamus, require the director of public safety to equip the ward.

It was also held that the university directors could not, under the city charter, authorize private patients from whom compensation should be received to be taken into this ward, without the consent of the proper authorities.

ACUTE HEART DILATATION HELD WITHIN WORKMEN'S COMPENSATION ACT

The Maine Supreme Judicial Court holds, Brown's Case, 123 Atl. 421, that acute heart dilatation while shoveling snow from a roof is an accident within the Workmen's Compensation Act; and that, while the word "accident" is commonly predicated of occurrences external to the body such as wrecks, explosions, collisions, and other fortuitous mishaps, "an internal injury that is itself sudden, unusual and unexpected is none the less accidental because its external cause is a part of the victim's ordinary work."

VOL. CXXI, No. 3 NEW YORK, WEDNESDAY, FEBRUARY 4, 1925 WHOLE No. 2298

Cancer's Selfcontrol*

ALBERT C. BRODERS, M.D.
Rochester, Minnesota

The chief difference between the average benign neoplasm and the average malignant one is that the benign exerts more control over itself than the malignant. It cannot be said that any neoplasm has complete control of itself at all times, because the very fact that it grows shows that its control is not absolute, but fortunately for the human race, the majority of neoplasms do reach a point of absolute selfcontrol, or in other words, obey the law of the limitations of growth. Moles, warts, lipomas, myomas, and fibromas are good examples.

Benign neoplasms produce a structure in which the cells are practically indistinguishable from the cells of normal tissues, although the arrangement is somewhat different, and unquestionably a number of benign neoplasms function to some extent like the tissue they so closely imitate. An adenofibroma in a lactating breast will secrete milk, a myoma of the uterus will sometimes contract like normal uterine muscle if it is irritated with the point of a knife, and an adenoma of the intestine will secrete mucus.

All benign neoplasms, like the tissues which they imitate, produce regenerative cells as well as differentiated cells; otherwise they could not grow, because the differentiated cells do not reproduce. It is also reasonable to believe that the regenerative cells of benign neoplasms are more active than the regenerative cells of normal tissues, and that the regenerative cells of certain benign neoplasms are more active than the regenerative cells of others, because they grow faster than others. It may be that the regenerative cells of benign neoplasms are more numerous than those of normal tissues, and that the regenerative cells of some benign neoplasms are more numerous than those of others.

When benign neoplasms reach the point of complete selfcontrol, their cells either cease to regenerate, or they differentiate beyond the point of regeneration. If all the cells of a benign neoplasm have differentiated beyond the point of regeneration, there is only one thing left for the neoplasm to do, and that is to degenerate, and this probably often takes place, especially in myomas of the uterus. Degeneration seems to be one of Nature's methods of getting rid of neoplasms.

We are in the habit of saying that certain benign neoplasms are potentially malignant when, as a matter of fact, we have no proof that they are. It would be almost as reasonable to say that the lower lips of middleaged men are potentially malignant, because in the United States about one fourth of all epitheliomas are located on the lower lips of men. It is safe to say that most adults have at least one mole on the body, but the type of the epithelioma that often starts in a mole represents only about five per cent. of all epitheliomas. Only about one per cent. of myomas of the uterus become sarcomatous; therefore, neoplasms that show a malignant change in only one per cent. certainly should not be called potentially malignant.

In passing from benign to malignant neoplasia, the fact should not be lost sight of that the power of selfcontrol still exists, although to a gradually diminishing degree. A wart that has been growing slowly on the skin for a number of years may show evidence of increased rate of growth, and after it has been excised and examined under the microscope, cells are observed at its base that differ from those found at the base of the ordinary benign wart. They are larger, irregular, and hyperchromatic, and certain of them may show prominent nucleoli, and have invaded the adjacent structures. Such a group is immediately pronounced cancer. The regenerative cells at the base of this wart have undergone what von Hansemann called anaplasia, or a process of dedifferentiation.

MacCarty, in his studies on the histogenesis of cancer of the breast, observed the same type of cells in his secondary cytoplasia. These cells are still within the acini, but are indistinguishable from the cells of his tertiary cytoplasia, or definite cancer, in which the cells have broken through the socalled basement membrane. I believe that MacCarty's secondary cytoplasia is just as definitely cancer as his tertiary form, when found in the breast, the only difference being that the cells are still enclosed by the socalled basement membrane. These anaplastic or dedifferentiated cells appear to represent a new type, and are observed in all forms of malignant neoplasia, although they vary in shape and size in different types of malignant neoplasms. Sometimes cells that are indistinguishable from them appear in benign regenerative process, for example, in certain exophthalmic goitres.

*Section on Surgical Pathology, Mayo Clinic.

Copyright, 1925, by A. R. Elliott Publishing Company.

These anaplastic or dedifferentiated cells have various potentialities. I wish here to emphasize a good potentiality, or the power to produce cells that differentiate or reach a state of maturity beyond their ability to reproduce. This differentiating or controlling quality ranges from practically nothing to almost one hundred per cent. The cells of a neoplasm that show practically no tendency to control themselves, rapidly infiltrate the adjacent structures and, by utilizing the vascular system as a means of metastasis set up colonies in various parts of the body, which in turn keep on producing their own kind of cells, finally with a fatal result. On the other hand, if the cells of a neoplasm show a marked tendency to control themselves by differentiation, the neoplasm will grow slowly, and show very little tendency to metastasize; or if some of its cells do metastasize, they will in turn set aside the large majority to differentiate and build a structure similar to that found in a normal organ, which functions to some extent. The latter process is sometimes found in cancer of the thyroid, and if it were not in such a structure as a lymph node, one would be tempted to call it accessory thyroid.

Squamous cell epitheliomas control themselves by producing keratin, and if not keratin containing cells, cells that have differentiated beyond their ability to reproduce.

Basal cell epitheliomas control themselves by producing cells similar to the normal basal cells of the skin, melanoepitheliomas by producing melanin which is a product of the epithelial cells and indicates an attempt at selfcontrol. It seems like a paradox, but the blacker a melanoepithelioma, the longer the life of the patient. One patient observed at the clinic had had an eye removed on account of melanoepithelioma, fifteen years before. There were black lumps all over his body, which had been there for ten years. A black axillary lymph node was removed, and on microscopic examination the epithelial cells contained therein were found to be packed with melanin. Recent data concerning this patient have not been obtained, but he lived for ten years with general metastasis. I have never seen, and never expect to see a patient with a nonmelanotic melanoepithelioma, or the white blackberry type, that has lived ten years with general metastasis.

Masses of keratin are not uncommonly observed in lymph nodes produced by cancer cells, although no cancer cells are lying adjacent to it. It is reasonable to believe that these cancer cells controlled their growth by complete differentiation, thereby bringing on a spontaneous cure. It is also reasonable to believe that, if something can be discovered that will make malignant cell differentiate, we will have the key to the whole situation. This I believe is only possible in the hands of the chemist or physicist.

Malignant neoplasms need not necessarily be preceded by benign neoplasms; the large majority are not. Many are preceded by destruction of tissue, but others spring up without the slightest injury, so far as we know; the latter type should be called true spontaneous neoplasms. It would seem that this type can only be explained by heredity. Familiarity with the accurate and epochmaking work of Maud Slye makes such explanation conclusive. It is probable that a large proportion of the malignant neoplasms which we are prone to attribute to various types of trauma occur in persons who have inherited a tendency to malignant neoplasia. It is often said that cancer starts from one cell. This may apply to a small number of cancers, but by no means to the majority.

In studying epitheliomas, I have often seen multiple points of origin in the same neoplasm, and even the basal cells for a distance on each side of the main growth show malignant change, although they have not started to infiltrate. In diffuse cancer of the stomach, I have seen a large number of tubules in which the normal regenerative cells have changed to cancer cells, although they have not invaded the surrounding structures. It is common to observe a number of breast acini in the state of secondary cytoplasia, while in the same region, other acini are in the state of tertiary cytoplasia or definite cancer. It may be assumed that the malignant change that took place in the cells of the various tubules of the stomach, or in the various acini of the breast were activated by the same cause, so far as each organ was concerned, in other words, "the whole thing has gone crazy." (6).

In 1915 I began grading malignant neoplasms on the basis of cell differentiation, and during the following four years two thousand epitheliomas were intensively studied. Of this number 1,628 squamous cell epitheliomas were graded strictly from a microscopic viewpoint, on a scale of one to four and absolutely independent of the clinical histories. The basis of the grading, published in 1920, is as follows: "If an epithelioma shows a marked tendency to differentiate, that is, if about three fourths of its structure is differentiated epithelium, and one fourth undifferentiated, it is graded 1; if the differentiated and undifferentiated epithelium are about equal, it is graded 2; if the undifferentiated epithelium forms about three fourths and the differentiated about one fourth of the growth, it is graded 3, and if there is no tendency of the cells to differentiate, it is graded 4. Of course, the number of mitotic figures and the number of cells with single, large, deeply staining nucleoli (oneeyed cells) play an important part in the grading." The mitotic figures and the oneeyed cells are undifferentiated cells, and really should be considered only as such; however, when mitotic figures are numerous, especially if they are of an irregular nature, one is inclined to raise the grade to some extent.

I have previously published three papers on this subject (2, 3, 4), and now, after nine years of experience with the grading of epitheliomas, I believe that the system of grading should be slightly revised; that is, instead of a Grade 1 epithelioma in which about three fourths of the cells are differentiated and one fourth undifferentiated, should be substituted a Grade 1 epithelioma, one in which differentiation of selfcontrol ranges from almost one hundred per cent. to seventy-five per cent., and undifferentiation from almost nothing to twenty-five per cent.; a Grade 2 epithelioma, one in which differentiation or selfcontrol ranges from seventy-five per cent. to fifty per cent., and undifferentiation from twenty-five per cent. to fifty per cent.; a Grade 3 epithelioma, one in which differentiation or selfcontrol ranges from fifty per cent. to twenty-five per

cent., and undifferentiation from fifty per cent. to seventy-five per cent., and a Grade 4 epithelioma, one in which differentiation or selfcontrol ranges from twenty-five per cent to practically nothing, and undifferentiation from seventy-five per cent. to practically one hundred per cent. So far as an estimation of the ultimate result is concerned, this revision will have no effect on Grades 1 and 2, but will affect slightly Grades 3 and 4, because a small percentage of neoplasms, formerly classified Grade 3, will now be classified Grade 4. In other words, the most malignant of the Grade 3 neoplasms will be classified in Grade 4.

Up to November 1, 1924, after excluding the inoperable cases and the immediate postoperative deaths, complete data were obtained in 880 cases of graded epitheliomas.

Of the Grade 1 group, or cases in which there was from almost one hundred per cent. to seventy-five per cent. of selfcontrol, a good result was obtained in 90.20 per cent.

Of the Grade 2 group, or cases in which there was from seventy-five per cent. to fifty per cent. of selfcontrol, a good result was obtained in 62.16 per cent.

Of the Grade 3 group, or cases in which there was from fifty per cent. to twenty-five per cent of selfcontrol, a good result was obtained in 24.82 per cent.

Of the Grade 4 group, or cases in which there was from twenty-five per cent. to practically no selfcontrol, a good result was obtained in only 10.09 per cent.

Precancerous Conditions About the Rectum*

ARTHUR A. LANDSMAN, M.D.
New York

In looking over the statistics on the death rate from carcinoma, one is struck with the large mortality occurring in this disease among civilized races. This amounts to sixty to 151 for each 100,000 of the population (1), varying with the locality, and represents not only one of the largest single causes of death, but is relatively and actually on the increase all over the world. The official records of the New York State Department of Health show (2) that the death rate from carcinoma increased 29.8 per cent. between 1900 and 1915, and rose in this state from 32.3 to 104.8 for each 100,000 of the population during 1921. According to the United States Health Reports (3), the carcinoma rate has taken an upward trend in 1921, and is higher than for any earlier year in twenty-three of the thirty-four states for which it was tabulated. In trying to account for this increase it has been argued that it is more apparent than real, because many cases are now discovered which formerly remained unrecognized; that this argument is unsound becomes clear when we consider that the general death rate from other diseases has steadily declined in the same period,—in the case of tuberculosis this amounts to fifty per cent. in the past twenty years (4). The gastrointestinal tract seems to be especially vulnerable, showing an incidence of over fifty per cent. in mouth, stomach and rectum (5).

Various theories have been advanced to explain the pathogenesis of carcinoma; it has been asserted at different periods that it is due to an inclusion of misplaced embryonal cells (6), to a disturbance of the balance between epithelium and connective tissue (7), to a loss in the power of the differentiation of the cells (8), to an infective agent (9), to parasites (10 and 11), to heredity, drinking water, and many other causes too numerous to mention; none of these will account for its occurrence in every case, though such advances have already been made in the study of the disease that it has been produced experimentally in the laboratory (12, 13), and transplanted from one animal to another. Evidence deduced from a mass of clinical data points to the conclusion that it is attributable to no one single cause, and that identical factors are not present in all cases (14, 15). There is one outstanding feature common to a large group which has long been recognized; this is a tendency to occur in tissue which has been subjected to long continued irritation, persistent trauma or chronic inflammation. In some manner these produce a favorable soil for the implantation of cancer. Billroth gives it as his opinion that carcinoma almost never arises in the normal breast (16), von Bergman asserts that cancer of the skin without cutaneous lesions does not exist (17), and Ribbert holds that epithelial cells can never grow into connective tissue which has not been altered by injury (18). That these are important factors in malignancy becomes evident when it is seen how often its starting point is in certain inflammatory and hypertrophic lesions,—the precancerous state of Orth. The rôle which chronic irritation plays in the development of carcinoma is further emphasized in the studies of Murray, Leitch, Scott, Legge,

*Read at the annual meeting of the American Proctologic Society, New York, June 24, 1924.

Rowntree and others (19), which show that agents such as arsenic, paraffin, röntgen ray and other factors are capable of setting up changes which result in malignancy. The theory upon which this is based is that they cause protoplasmic disintegration in the course of which activating substances are produced which stimulate cellular growth and cause the formation of a typical gland structure. Clinically this is illustrated by carcinomatous degeneration which occurs under similar conditions in various parts of the body. For example, in the skin most growths of this type have their origin in warts, moles, nodules, ulcers, scaly patches, leucoplasic areas, etc., and when these are subjected to trauma or chronic irritation many of them become the starting points of carcinoma. Keen and Bloodgood report removal of moles which had become malignant in sixty-five patients. In seventy-six others they excised pigmented growths of the same type in the precancerous stage, in none of which there was a recurrence or death from malignancy (20). Leitch reports that the papilloma and epithelioma of paraffin workers is preceded by skin lesions. In carcinoma of the lip, tongue and cheek there is often a history of chronic irritation from the rough mouthpiece of a pipe, broken or jagged teeth, chewing of irritating substances. Carcinoma of the uterus most often begins in portions injured at childbirth, and has its starting point in cervical erosions, ulcers, cicatrices and hypertrophies, and as a matter of fact is very rare among women who have never borne children. Coley reports 970 personal cases in twenty-three per cent. of which local trauma from chronic irritation was the determining factor in malignancy (21). Smith quotes from the records of the Mayo Clinic, showing that sixty to seventy per cent. of carcinomata of the stomach begin in gastric ulcer, and Bland Sutton writes that malignancy of the gall-bladder is intimately associated with gallstones and biliary concretions (22).

Analogous conditions exist about the anorectal region which are likely to result in carcinomatous degeneration under suitable conditions. Neglected ulcers, fissures, cracks, postoperative wounds, chronic eczema of the anal skin, benign tumors which are kept in a state of chronic irritation from stool, scratching or friction from clothing, may when the time is ripe take on a malignant character. To quote from Sutton: "Some chronic inflammatory change often precedes anal carcinoma, such as piles or fissure, and it has been known to begin at the mouth of a chronic fistula" (23). Some years ago I saw a woman who had been operated upon for an anorectal fistula of long standing; three months after her operation clinical evidence of carcinoma developed in the scar, of which she died later. I operated upon a woman of middle age for a pedunculated growth which had existed ten years and had been diagnosed as piles because it protruded at stool, but gave no other symptoms except a severe grade of anemia. At the attached portion of the growth there was an ulcerated area the size of an apple seed, upon which the report of the pathologist read, "Adenoma strongly suspicious of malignancy." I resected a papillary tumor of the rectum in a patient of forty, who gave a long history of intestinal disturbance, protrusion and bleeding from the rectum. She has at this writing a thickening of the wall and infiltration which appear to be a recurrence of her trouble, although the pathological findings are negative for malignancy. It is well known that many cases of polyposis of the colon and rectum ultimately undergo a malignant change, fifty per cent. according to Ewing (24), while Lockhart Mummery states unreservedly that multiple adenomata are definitely precancerous, all of them eventually undergoing a malignant change (25).

In the past six years I saw three cases of colitis polyposa in all of which there had been a history of rectal trouble lasting over a period of years. In two of these patients carcinoma of the colon developed and the patients died, the third is still living in a hopeless condition from general carcinosis. One of these was a man under thirty, who suffered from ulcers of the bowel with a discharge of mucus, pus and blood for a number of years. When he came under observation he showed a rapidly increasing number of papillary tumors and died two years later of carcinoma of the sigmoid. It appears probable that his original ulceration was a benign condition which from chronic irritation resulted in the precancerous adenomata. Mayo reports forty-two cases of diverticulitis of the large intestine, in thirteen of which carcinoma coexisted, and draws the conclusion that infection, irritation and trauma established the precancerous condition (26). Infestation with bilharzia hematobia has been found to be the cause of vesical and rectal tumors in tropical countries, and Ferguson reports forty cases of this nature (27). Exner cited by Pennington records one case in which pile tumors assumed sarcomatous degeneration (28). One could quote other instances of this character from the literature, but it must be quite clear by this time that innocent lesions of the anorectal region not infrequently undergo malignant change. For convenience they may be set down in the following grouping:

1. Any indolent sore, erosion, crack, fissure, ulcer or wound which in the absence of unfavorable constitutional conditions fails to heal within a reasonable time should be looked upon with suspicion. This is especially true when it occurs at the rectosigmoid or mucocutaneous junction, at the base of one of the valves, the point of attachment of supposedly innocent growths, about folds and situations where there is an abrupt change of structure, or locations where it is exposed to repeated bruising.

2. Benign neoplasms which are soft, highly pigmented, multiply in great numbers, grow rapidly, extend steadily, recur after removal, have a tendency to grow on a broad base rather than an elongated pedicle, must be regarded as potentially malignant.

3. Any long standing irritative disease or process about the rectum such as fistula, diverticulitis, the skin changes which follow chronic anal pruritus, perianal dermatitis or eczema, leucoplasia, stricture and prolapsed rectum may in time acquire malignant characters.

4. Inflammatory lesions due to syphilis or tuberculosis may have carcinoma engrafted upon them. As early as 1872 Hutchinson recognized that certain syphilitic lesions of the mouth were precancerous.

5. Malformations and congenital tumors may occasionally, though rarely, become malignant.

CONCLUSIONS

1. There is good ground for the belief that carcinoma does not arise from normal tissue.

2. Benign growths and pathological processes of the anorectal region are favorite sites for the development of malignancy.

3. The removal of these in an early stage is a truly preventive treatment of cancer.

Influence of Pulmonary Tuberculosis on the Evolution of Pregnancy and the Offspring

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland

Out of a total of thirty-five cases reported by Sakka in his thesis (Paris, 1918) there was not a single miscarriage; there were seventeen full term labors, four at eight months and a half, ten at eight months, two at seven months and a half, and two at seven months. Out of a total of twenty-two cases reported by Grisolles, there were seventeen labors at term, three at eight months, and two miscarriages at four months. Of twelve cases recorded by Dubrenith, ten labors took place near term; the other two patients miscarried. Proust gives the following statistics from the Charité Hospital, from 1898 to 1902. Of fifty-two women, thirty went to term, four to eight and a half months, two to seven and a half months, four to seven months, and one miscarried at five months. Hence it would appear that in maternal pulmonary tuberculosis, premature labor is as frequent as full term labor, and that miscarriage is infrequent.

Experimental data are similar to clinical results. In female animals inoculated before fecundation, Landouzy found that gestation usually went to term, while in females inoculated during gestation, the evolution of the pregnancy varied with the time the inoculation was made and especially with the virulence of the bacillus inoculated. The animals rarely miscarried. Most observers maintain that tuberculosis has little influence on the evolution of pregnancy.

As to the offspring being born with tuberculosis, one must consider two questions, namely, hereditary contagion and hereditary predisposition. Direct transmission of the maternal tuberculosis to the fetus does occur, although exceptionally, and has been demonstrated by clinical data, likewise experimentally. Landouzy and Martin inoculated pregnant guineapigs with the organs of fetuses issued from tuberculous mothers and in some cases bacilli were found in the viscera of the young animals and in the umbilical vein. Other experiments carried out by Aviragnet, Londe, and Thiercelin with placentas from tuberculous women, by Bar and Rénon with blood from the umbilical vein, and by Herrgott with the amniotic fluid, have been positive.

How does infection take place when the fetus is born tuberculous? It may be derived from the mother from infection of the ovum, but as Strauss has pointed out, this is a hypothesis difficult to prove or even to accept, although it cannot be discarded. In order to be accepted one must admit that the presence of the bacillus or its toxins within the ovum will not prevent fecundation or migration of ovum during the entire embryonal life.

If infection takes place during the fetal period there may be transplacental contagion in which case the mother must present a bacillemia, which is not the rule in pregnancy. It is only after labor that tuberculosis becomes aggravated and generalized.

Then again, for infection to take place during gestation the placenta must be permeable to the bacillus and some observers maintain that such is the case upon the condition that the epithelium of the villosities is pathologically changed. Landouzy even suspected that the bacilli could pass through the placenta without leaving any trace of this passage.

Then there is the question of placental tuberculosis. Of thirty-two placentas from tuberculous women, Schmorl found distinct bacillosis in fourteen; Schlimpert in four out of seven, and Bar, four out of twelve. Nevertheless it must be admitted that this is a rare condition and hard to detect. In these circumstances placental infection of the fetus may occur if, as Bar points out, the placenta be regarded as a tuberculous abscess which being squeezed by the contractions at the end of pregnancy, and during labor, forces the bacilli immobilized in the intervillous fibrinous masses into the fetal circulation.

The possibility of infection of the ovum by the father has as yet not been proved clinically or experimentally. Hence, one may conclude from both clinical and experimental data that congenital tuberculosis is unquestionably rare, and that in the majority of cases the fetus is born intact.

Now, although the fetus is not born tuberculous in the bacteriological sense of the word, it is predisposed. The offspring of phthisical parents inherits cells which react quite as badly as those of the parents against tuberculosis infection. The offspring has inherited, not the tuberculosis, but the aptitude to contract the disease. Therefore, the heredity of soil—hereditary predisposition—is at present generally accepted. It is above all the future of children born of tuberculous mothers that seems favorable to this theory.

As to the future of the offspring in Sakka's thirty-five cases, ten died in hospital, nine were discharged in a mediocre condition, while sixteen were in good health. Among the ten that died, one died a few hours after birth, three were at seven and seven and a half months term and were put in an incubator, one was born dead, while the remaining three died within ten days after birth.

Voron's statistics covering six years at the Lyons Maternity, show that sixty-eight per cent. of the offspring of tuberculous mothers had died. Planchu and Gardere, of Lyons, came to similar conclusions. According to Ascoli, fifty-five per cent. die during early infancy, of which thirty-three per cent. die from tuberculous meningitis. Hamburger gives a proportion of twenty deaths out of fifty-one infants.

Although low, the value of the product of conception is far from being negligible. In point of fact, Voron's statistics show that thirty-two per cent. of the offspring were alive six years after birth. It is also evident that the future of children born of phthisical parents must largely depend upon the social situation of the latter.

34 Rue Bellot.

Chronic Intestinal Stasis in Epilepsy*

A. WHITE ROBERTSON, L.R.C.P. and S. Edin.
Glasgow, Scotland

In the study of epilepsy it seems clear that whatever the actual exciting element the vascular system is the main source of the epileptic phenomena, either alone or as a carrier of toxic agents, and the work that has been done experimentally by the advocates of both views has been very considerable in the last twenty years. Cells cut off from their circulation, even momentarily, show a reaction towards acidity, and this acidity factor must not be lost sight of in the interpretation of the experimental results recorded by the mechanical and vascular theorists. Faradization and epinephrin will also blanch pial vessels and produce epileptiform convulsions. The proteoses of Cuneo, to be presently described, have the same effect when painted on the cortex. Lastly, lactic acid given intravenously will also produce convulsive seizures. Acidosis, therefore, whether produced locally or remotely, would appear to play a considerable rôle in the production of the epileptic convulsion, and the work of Cuneo (1) during the last nine years at Genoa goes perhaps further than that of any other investigator to establish its importance.

Cuneo established the presence, in the blood of persons who had just had an epileptic seizure, of a substance which he identified with the proteoses, and this substance introduced intravenously into animals faithfully reproduced the epileptic phenomena. At the same time he showed that the urine of these persons contained an extraordinarily high percentage of organic acids. Other features were a retention of total nitrogen, an increase in the nitrogen content, and continuous acidity of the feces. Comparative tests in epileptic groups with a protein rich and with a carbohydrate pure diet next gave unexpected results, the acidosis in the former group being reduced, with a corresponding improvement in the severity and number of the fits, while there was a percentage increase in acidity in the second group, and the fits increased in number and severity. It was next established that the fault in the starch metabolism occurred in the first stage of conversion to the disaccharides, maltose, lactose, cane sugar, etc. Normally this takes place through the action of the amylolytic ferments, the subsequent conversion of maltose being effected by maltose ferment through hydration into glucose. The failure in the first stage resulted, in the absence of sufficient amylolytic ferment, in the production of a more or less intense concentration of organic acids—acetic, butyric, lactic, tartaric, etc.—and these, which should normally

*An address to the British Medical Association, Tunbridge Wells Division, February 27, 1924. Submitted to the *British Medical Journal* for publication May 31, 1924.

have been united with alkaline bases in the small intestine, passed in the epileptic into the blood stream and urine unchanged. The alkaline salts in normal individuals are oxidized—if ammoniacal through carbonate of ammonia into urea, if sodium into sodium carbonate, and this is the vitally necessary salt for maintaining the alkalinity of the blood and tissues. Cuneo concludes from his work that this transformation of organic salts into sodium carbonate begins in the mucosa of the small intestine and is completed in the liver, whence the sodium carbonate is returned to the gut with the bile. Lack of bases favor the production of acidosis, while a sufficiency of sodium tartrate favors the activity of the liver ferments and the production of sodium carbonate. If sodium acetate or tartrate is introduced directly into the circulation it causes typical epileptic convulsions, and Cuneo was able to remove from the carotid artery of the animals used a substance which proved to be a proteose.

The source of these proteoses Cuneo found in the reduction of that fundamental constituent of all cellular nuclei, nucleohistone, and in the case of the serum and leucocytes of the blood also this reduction takes place under conditions of acidosis due to the concentration of organic acids. In an acid medium he was able to demonstrate the reduction of nucleohistone from both these sources into an innocuous acid and a toxic base having the chemical and biological properties of nucleinic acid and of proteose. Introduced intravenously in dogs the latter not only produced typical epileptic convulsions, but the postmortem appearances in dogs dying in status epilepticus so induced were identical with those found in the viscera and the brain and its coverings in persons dying of proteosemia (albumosemia), and as described by Tanzi and Lugaro in their findings in patients who died in typical status epilepticus.

He believes that albumosemia exists in epilepsy and that this is caused by an insufficiency of the alkali forming function in the liver and the small intestine so that the acid organic salts, which are transformable into sodium carbonate, do not undergo this metabolic change, but enter the circulation and cause a division under certain conditions of the nucleohistone element and the nucleoproteids into nucleinic acid and proteoses. These latter remain free and exhibit their convulsive action.

Localized acidosis in derangements of the circulation may also set free albumoses, or it may be other toxins, as in Jacksonian seizures; and in the convulsions associated with craniocerebral injury with scar adhesions, brain abscesses, circumscribed areas of encephalitis, brain tumor, cysts, general paralysis, cerebral arteriosclerosis, the acidosis produced by interference with the vascular supply, may as suggested by Osnato (2), determine the release of proteoses locally in cells cut off from their circulation, and so excite the convulsions associated with these conditions. In general paralysis and arteriosclerosis, and probably also in encephalitis, the vascular disturbances and the local cellular destruction processes in the brain elements are ideally combined to produce generalized convulsive seizures.

A little over two years ago it was my privilege to address you on the possibility of proving a close connection between epilepsy and chronic intestinal stasis. More recently I have published a preliminary report (3) on a small group of epileptics treated on lines directed exclusively to the relief of the gastro-intestinal conditions found associated in these patients with the epileptic phenomena. Today, thanks to Cuneo's researches, I find myself in a stronger position to press the importance of chronic intestinal stasis as a factor in the pathogenesis of epilepsy. I have had opportunity of studying in very great detail twenty-seven cases of epilepsy. In all of these a full personal and family history was obtained, and each patient was examined, system by system, for indications or history of chronic toxic conditions. The blood, menstrual blood, urine and stools were examined, and the condition of the uterus, urinary bladder, teeth, tonsils, nares and sinuses investigated. Thirteen cases were x rayed with bismuth meal and barium enema, and eight of these were operated upon for conditions of advanced stasis affecting the general health. In every epileptic examined the clinical and laboratory evidence was eloquent of considerable chronic intestinal stasis and widespread mucosal catarrh of the intestine, as described first by Lane. As in the early group reported treatment has, in every case, been directed primarily to the relief of the intestinal condition.

Of the twenty-seven cases examined, only twenty can be reported upon as still under my personal supervision, and of these five are not yet sufficiently long under treatment to enable me to include them in any statement of results. I can, however, report on fifteen cases sufficiently long under treatment to be included in such a return.

In five cases there has been complete arrest of epilepsy over a period of from one to three years. Three other cases show immunity over a period which just fails to bring them into the same category. Three cases show a lengthening interval and decrease in severity of the attacks. Three cases show no improvement at all, including one with some injury to the scalp from burns. One patient died from pulmonary embolus following operation. When it is remembered that bromides and luminal have been excluded from the treatment, and that the carrying out of my instructions has been in many and various hands, I think I may fairly claim that the methods of treatment I have adopted have yielded results which go some way towards proving a close association between demonstrable chronic intestinal stasis and epilepsy.

The following points have emerged in the examination of cases. The feces were examined in all for intestinal parasites and their ova, with negative results. Fourteen cases showed undigested starch in excess, and practically all cases showed an acid reaction in the feces. Bacilluria occurred in fifteen cases, albumin in four, sugar in one, and the average total acidity of the twenty-seven cases was considerably above normal. The blood pressure readings varied: under 100 mm. four; under 110 mm. two; under 120 mm. six; under 130 mm. five, under 140 mm. two; 150 mm. or under, four. So that the average was 121.4 mm. The pulse pressure averaged 43.2 mm. Of eleven females four showed definite goitre, and four marked amenorrhea. Tonsils were found enlarged and septic, or had been

already removed, in twelve cases. In one case a suppurating antrum had been treated. Sixteen cases gave definite evidence of chronic catarrh of mucous membranes other than the gastrointestinal tract. Enuresis was reported in four cases; sleepwalking in four; urticaria in seven; stammering in three; migraine in three; asthma in one. A family history of epilepsy was found in eight; stammering in eight; asthma in three; migraine in three; urticaria in two; chorea in one. In no case was a syphilitic history obtained either in the patient or in the parents. In two cases the parents were first cousins. Congenital defects or malformations were found in five cases; undescended cecum in one; maldevelopment of the genital organs one; persistent deciduous teeth one; hypoplasia of enamel two; impacted molars two; there was a personal history of active tubercle in childhood in one patient, and in one case the family history showed tubercle, involving three members of the family, whilst in another case there was a family history of chronic alcoholism in the father.

The results of treatment generally have been, I think, encouraging; and, if all the operational cases have apparently not done better than the unoperated group, it must be remembered that these were cases calling definitely for operation on the grounds of intestinal stasis alone, and further, that with the two exceptions where colectomy was done, the removal of a controlling appendix and acquired bands or adhesions still left the edematous, turgid, congested, and perhaps denuded mucosal surfaces for aftertreatment. Were not colectomy so dangerous an operation I should be inclined to resort to it more frequently in epilepsy, but as a general rule the treatment of patients not operated on, or otherwise operated on, is necessarily prolonged, and results cannot be expected at once in cases of longstanding chronic mucosal catarrh. Yet the immediate cessation of epileptic attacks from the date of operation in several cases has been a very striking experience.

There is much to investigate in every individual case, besides the degree of involvement of the colonic tube. The extension of the chronically catarrhal and infective processes to the duodenal and upper jejunal area, and to the stomach, is a common feature in all cases of intestinal stasis at all advances, and it is this extension which links my observations with those of Cuneo. I believe that the leaking septic tank is the first cause of epilepsy, and that the later involvement of the small intestine and liver in chronic intestinal stasis is the next step towards the failure of the alkali reserve which Cuneo has described. And I further believe that the graver the involvement of the mucous membranes of the body generally, but particularly of the colon, in the chronic catarrhal processes, the greater the output of organic acids and the more profound the demineralization of the tissues and cells of the body. Acidosis is the feature of epilepsy, and is associated with persistent acidity or hyperacidity of the feces and urine. In the presence of such an acidosis the destruction of the nucleohistone of *mucosal cells* is constant and widespread, and proteosemia results on a large scale independently of the actual pressure of organic acids in the blood stream itself. I am confirmed in this view by the constancy with which my patients attribute their attacks to indigestion, to constipation, or to the presence of offensive stools, and by the good results of a return to sound habits of colonic hygiene. It is also my experience that the more chronic and extensive the colonic catarrh, the more grave the epilepsy in severity and frequency. Moreover, the more rigorously the system of treatment is carried out the more rapid and complete the improvement. This treatment is directed to the restoration of the function and amenity of the gastrointestinal tract, and particularly to the reduction of the septic catarrhal process; but no treatment will prove successful which does not also provide for a vitamine rich diet, for remineralization, for endocrine and general hormone reinforcement, and for the removal of septic processes wherever recognized. Where surgical relief of stasis is obviously necessary it must be carried out.

The part played by heredity is still a matter of dispute, but the figures I give in my own small series are sufficiently striking, not alone for epilepsy but for the closely allied explosive conditions—migraine, stammering, chorea, asthma, and urticaria. Sargent reviewed over eighteen thousand cases of craniocerebral wounds with skull defect resulting from war injuries. Of these in about eight hundred only, or four and five tenths per cent., epilepsy developed. I have, in the last five years, made a complete clinical and laboratory examination of not less than five hundred cases of typical chronic intestinal stasis; yet of these only twenty-seven have shown any signs of epilepsy, say five per cent. In these five hundred cases are many showing varying degrees of other nervous conditions—nervous exhaustion, phobias, borderland cases, dementias, sclerosis, etc. But unless the vulnerability of the cortex to certain specific toxins in certain individuals or families is accepted, we have no other explanation for the very occasional appearance of epilepsy in a condition so common as acidosis.

All of our present experimental methods of inducing epileptiform convulsions in laboratory animals, such as faradization, artificial anemia or acidemia, painting the cortex with epinephrin or proteoses, etc., fail to explain the general immunity of the vast majority of persons to the epileptiform convulsions so induced in laboratory animals. I, too, like Osnato, am convinced that it is on the lines of Cuneo's work that the great advance is to be looked for. My own work on stasis offers, as explanation of the failure of starch reduction in the small intestine which he has described in epileptics, the fact that extension of the catarrhal processes to the upper small intestine from the colon is due to mechanical obstruction at the ileocecal entrance and at the duodenojejunal junction secondary to overloading of the static colon. A further factor must surely be the subversion of the hepatic functions by the high acid and toxin content arriving by the portal channel. There is, however, this also to be said. The destruction of mucosal cells in the colon on a wide scale in stasis releases into the vascular system toxic agents, which, coming from such an origin, must have a specific affinity for mucosal cells at a distance. Only thus can we explain the frequency and the chronicity of catarrh of remote mucous membranes, nasal, bronchial, uterine, which is so constant a feature in chronic stasis cases, and which

proves so intractable until the main colonic reservoir of these toxins is overhauled and repaired. Closer study of the leaking septic tank will yet yield a most fruitful contribution to medical science, and a further step to the solution of many problems hitherto accepted as insoluble. These will almost certainly include a large proportion of chronic functional disorders within the province of neurology and psychiatry, and with them the problem of epilepsy will certainly be advanced definitely nearer to complete solution.

I have to acknowledge gratefully the loyal support and cooperation of the many general practitioners who have carried out my suggestions in treatment, and the staff of the various hospitals and homes where operations have been performed. To Dr. A. C. Jordan and to Sir W. Arbuthnot Lane especially, my thanks are due for the great skill and interest they have shown in the x ray and operational sides of the work.

Pathological Impulses or Currents

HIRAM BYRD, M.D.
Bradentown, Florida

This is a sort of epitome of conclusions growing out of studies of the nasal ganglia by nerve blocking methods, and upon which studies certain publications have been based (1, 2, 3, 4, and 5).

An impulse originating in a nasal bloc may travel to, and be registered in, remote parts of the body in the form of pain or other pathological phenomena. That impulse, whatever it is, is the subject of this article. For the present it will be called simply a pathological impulse.

The evidence of the existence of such an impulse is like the evidence of the existence of electricity —it is known only by its manifestations.

Now it is a well known fact in physiology that cocaine, or other local anesthetic, may be applied to the trunk of a nerve, and that this effectively blocks the passage of all impulses till the effect of the anesthetic has passed away. It is also well known that when a local anesthetic is applied to a nerve that is transmitting a sensation as of pain to the brain or centre of consciousness, the pain is blocked off. This is what occurs when after a tonsillectomy (1) the pain from the tonsillar region is blocked off by cocainizing the nasal ganglion. The pain from the tonsil is transmitted via the nasal ganglion to the centre of consciousness, and all one has to do to arrest it is to cocainize the nasal ganglion, i. e., the nerve between the locus of distress and the brain. But in the case of say a traumatic corneal ulcer, the pain of which can also be arrested by cocainizing the nasal ganglion, the process is quite different. The pain from a corneal ulcer is not transmitted to the centre of consciousness via the nasal ganglion: for if it were, one would only have to cocainize the nasal ganglion to anesthetize the cornea, which is not the case. Indeed the cornea is quite as sensitive to the application of an irritant with the nasal ganglion under profound anesthesis as without. So that we can put this down in our frame of reference: pain from the cornea is not transmitted to the brain via the nasal ganglion.

And yet, as above indicated, the exquisite pain of a traumatic corneal ulcer can be completely blocked off and the eye made quite comfortable by cocainizing the nasal ganglion of the same side. This phenomenon calls for an explanation.

In connection with a traumatic ulcer of the cornea, it is worthy of note that in some instances a considerable corneal trauma may be sustained with little pain, whereas in other cases, slight trauma is followed by intense pain. I recall the case of a negro (2) who was driving a metal pipe into the ground with a hammer when a piece of metal dislodged and struck him in the eye. Presumably it went through the cornea, for it left no trace in the sclera, and it lodged pinioning the iris to the crystalline lens. It could be seen quite plainly as a bright object in the iris, close to the margin of the pupil, which was a little distorted. And yet it was all so painless that he did not seek medical aid for a week and when he did, it was because of what he *saw* rather than what he *felt*. There was no photophobia and no inflammation, and the boy was using his eye apparently without discomfort, but as he expressed it, he could see something in it. This represents a case of extreme trauma with a minimum of pain.

On the other hand, a party was out on a picnic. One person stepped on a twig and it struck another in the eye, making a microscopic abrasion of the cornea. This became quite painful in a few hours, but (and this is important) the pain was easily blocked off and the eye made comfortable by cocainizing only the nasal ganglion.

Again, a case of iritis, cause unknown, was under treatment. It was found that the pain could be readily blocked off and the eye made comfortable by cocainizing the nasal ganglion of the same side. But the relief lasted only a few hours, ususally three to five. Now, the patient discovered for himself that when he slept on the affected side his nose "corked up" and that whenever his nose "corked up" his eye grew worse.

Putting all of these phenomena together, phenomena which are not accidental or occasional, but uniform, and can be checked up by any one, the conclusion is forced that the pain in these cases is

augmented by something being sent to the locus of distress via the nasal ganglion. It is that something which in this connection is referred to as a pathological impulse; pathological because it emanates from a locus of pathology, and because it augments, or possibly under some circumstances initiates a pathological disturbance at the locus of registration.

I have referred to the case of the traumatic ulcer of the cornea as an instance in which the proof is definite and positive that the pain is not transmitted to the centre of consciousness via the nasal ganglion. Another case will illustrate it possibly more forcibly. Mr. R. (3) working in a planing mill had his fingers so mangled that one had to be amputated; and the case was followed by infection, and became quite painful. Now it was found that the pain in this case could be blocked off at the nasal ganglion of the same side, and the hand made comfortable, which invariably lasted two or three hours—during the life of the cocaine. Here again was proof that the pain of the hand was not being transmitted to the centre of consciousness via the nasal ganglion, for after blocking it off, the hand was still quite sore, and sensitive to pressure, which would have not been had the pain been passing the nasal ganglion. And the way blocking the nasal ganglion gave relief was by keeping something away from the hand,—something that was augmenting the pain,—a pathological impulse.

Another instance. Mrs. W. (4) was suffering from cancer of the uterus. It was far advanced, inoperable, and the end was being awaited, which came some two months later. But she also had a nose trouble and in attempts to give her relief for some of her nasal symptoms, the left nasal ganglion was cocainized, when it was found that that arrested the uterine pains, which at this time were radiating up the back and down the lower extremities. But blocking off the pain did not block off the uterine soreness, which was as acute as before.

With this evidence in hand, it would seem that the proof of the pathological impulse being an entity is established. It now remains to note some further phenomena in connection with it.

There seems to be no reason *per se* why a pathological impulse might not originate in various parts of the body, as perhaps they do; but as yet the proof is limited to the nasal blocs.

If, and since, pathological impulses originating in a nasal bloc may be propelled to and registered in almost any part of the body, the question naturally arises, why does a given impulse go to, say the right knee, when it could go to the left wrist? Why a cough, when it could be a sneeze? Or a cough today and a sneeze tomorrow? Why arthritis, when it could be neuritis? or lumbago? or asthma? or headache? Is it the nature of the impulse that makes it go to a certain place? or the reception offered it? Perhaps the final answer to that question is locked up in the future, but we have already some strong presumptive evidence. And all evidence points to the interpretation that a local pathology attracts a pathological impulse. For instance, Mr. G. contracted sciatica in the right leg. For three days or so, he was almost *hors de combat*. During this time he stumbled and came near falling, and in his attempts to regain his balance strained his left leg. Immediately the pain left the right leg and took up its abode in the left leg and he was laid up with sciatica of the left leg for two months. It would appear from that that the strain incident to the stumble put the left leg in a receptive mood and that the impulse was attracted accordingly. Again, in the case of

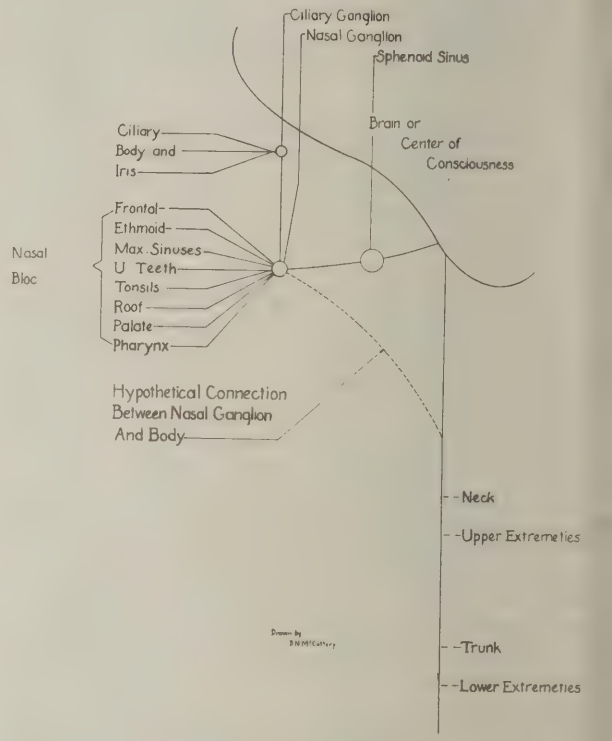

Fig. 1.—Diagram showing course of disturbances originating in a nasal bloc.

traumatic corneal ulcer above referred to, and this is only one of many such cases that have come under observation, there was evidently a loose impulse, too weak, perhaps, to excite symptoms *per se* but quite strong enough to drive a corneal ulcer into agonizing pain.

The other case above referred to, Mr. R., who sustained the loss of his finger, and a subsequently infected wound, is a striking instance of a local pathology attracting a pathological impulse. Mr. R. was known to have rheumatic pains from time to time, and during the prevalence of this painful hand he had no rheumatism. Possibly the entire pathological current spent itself in its concentration about the hand. It is a common phenomenon in the case of rheumatics that sustain an operation—that the rheumatism abates during the period of convalescence from the surgical disturbance.

Since the nasal ganglia are the points at which these pathological impulses may be arrested, it is important to know just what structures may transmit pathological impulses via these ganglia. We have only to turn to the anatomists for answer. The terminal branches of the nasal ganglia, right and left, are distributed respectively to the mucosa of the right and left nasal cavities and paranasal cells (with the exception of the sphenoid) tonsils, upper teeth, eustachian tubes, roof, palate, and pharynx. These regions I have referred to collectively as the nasal blocs.

The accompanying figure, which is partly hypothetical, and wholly diagrammatic, illustrates what happens when a disturbance originating in a nasal bloc, reaches proportions that impel escape. The nasal ganglion corresponds with a high degree of accuracy with the central office of a telephone exchange. It is the central station for the entire bloc. It is also the long distance station for regions beyond, as the eye, the sciatic nerves, the uterus.

The nasal ganglion, it will be observed, has direct communication with the brain and so all loci in the nasal bloc have easy access to the centre of consciousness. But these several loci have communication with other parts of the body, via the nasal ganglion, but not via the centre of consciousness. The ethmoid, for example, has a nerve communication via the nasal ganglion, and the ciliary ganglion to the ciliary body and iris. It also has communication with the shoulder and arm, via the nasal ganglion, but the rest of its path I know not.

Circuits.—The right and left nasal blocs do not seem to communicate above the neck, for pain or other disturbances in the region of the face and head can be blocked off only from the same side, but each nasal bloc seems to have open communication with both shoulders, arms, all parts of the trunk, and both lower extremities, even to the toes. Sciatica may be blocked off from the same side, or from the opposite side, as the case may be. Thus we seem to have two complete nasal circuits, a right and a left; the right including the right nasal bloc and the entire trunk and extremities, and the left including the left nasal bloc and the trunk and extremities, the two circuits overlapping throughout the trunk and extremities, but separate in the nasal region. From this it is seen that a pathological impulse, as lumbago, for example, may be emanating from the right nasal bloc or from the left, and the only way of telling which is by the blocking test. It is further conceivable that there may be other circuits, as an infected gallbladder, or kidney, or intestinal adhesion. As yet we have no light on such circuits except what we get from inference.

Growing out of this anatomical structure and these nerve blocking phenomena the author formulated the following law:

A disturbance originating at any point in the nasal bloc may be transmitted to any other point in the bloc, or to regions beyond, but in so doing it must pass via the nasal ganglion of the same side, and can accordingly be blocked off at that point.

Another question that is persistent in its demands for an answer is whether a pathological impulse can initiate a local pathological condition. That it can augment one, there is not the slightest doubt. And when a local pathology is augmented by the advent of a pathological current there is a vicious circuit set up, in which each tends to accentuate the other. But whether it can initiate one, might be an open question.

Mr. W. had a nasal disturbance that was resulting in rheumatism of the right arm—rheumatism or neuritis—at any rate a pain—which could readily be blocked off from the left side. It was found that after removal of a part of the right middle turbinate that was impinging on the septum, the pain abated except when he mowed the lawn. At such times the pain would return. It could still be blocked off, however. In this case it would seem that there was a residue of current still lurking about in the nasal bloc, but not enough to excite pain. When, however, the toxins of fatigue were added to the arm, then the combined effect of the toxins and current was sufficient to induce pain. Indeed it is conceivable that in the presence of rather strong current that an extremely slight local disturbance is sufficient to attract the current and this in turn to augment the local trouble, and thus pull harder on the current, etc.

I have seen this interpretation supported again and again by a patient with a known pathological current who finds that while lying in bed on the back, pain in the knees may be excited by straightening them out so that the muscles are taut, while flexing them gives relief. That it was emanating from the nasal bloc has been again and again checked up by blocking. It is a common expression among people that a draft on the back will put the shoulders to aching. I have seen this occur, just the chilling being sufficient to attract enough current to assert itself, and have then checked up the results by blocking off the pain at the nasal ganglion. So that it seems certain that minor local disturbance is quite sufficient to attract any loose current that might be abroad and thus initiate a set of symptoms that gradually gather momentum.

Causes.—It need only be mentioned that pathological impulses may emanate from an abscessed tooth, an infected tonsil, or a sinusitis. But it should be emphasized that pathological impulses may emanate from a sinusitis where there is no evidence of infection (3). There is still another group of cases in which the most painstaking examination using all the devices at our disposal fail to discover a pathological lesion in the nasal bloc and yet which are suffering from pathological impulses that emanate from the nasal bloc as shown by the fact that they can be blocked off. That monumental work of Sluder and Wright on the pathology of the nasal structures I think throws light upon such cases. Wright says: "It would probably be difficult to find an adult individual in a temperate or cold climate who does not present an example of this bone change within his nasal chambers, which we have a right to call pathological. It is only exceptionally that the symptoms to which it gives rise are sufficient to cause him to seek relief. When, however, it causes bony occlusion of a nasal fossa by means of a spur or deviation, when it stops up an ostium of an accessory nasal sinus and prevents proper drainage, when it impinges on a branch of a sensitive nerve or involves its peripheral distribution marked symptoms and a long train of the consequence may ensue." From this one would expect to find cases suffering from nasal disturbances that defy, during life, minute interpretation. It is such cases as these that are referred back from the rhinologist with a negative report, and which cases a little adroit nerve blocking will often clarify.

Treatment.—Treatment will not be considered in this connection. What is sought is a more perfect understanding of the principles involved; this achieved, the line of treatment will at once become obvious.

SUMMARY

1. Pathological impulses are, within the meaning of this article, real entities.

2. Pathological impulses may originate in either nasal bloc (or possibly elsewhere), from whence they are, or may be, transmitted to the remotest parts of the body.

3. Pathological impulses, it is conceivable, of such low amperage as to produce no appreciable effect, may be abroad in the body.

4. Pathological impulses are attracted to pathological loci, wherever such loci occur on the circuit of the impulse.

5. A pathological impulse attracted to a pathological locus cooperates with the latter in establishing a vicious circuit.

6. It is conceivable that a pathological impulse may take advantage of a slight impairment, such as fatigue, or momentary chilling of a part, or slight strain, to insinuate itself in and thus set up a vicious circuit.

7. A pathological impulse originating in either nasal bloc is not transmissible to its fellow of the opposite side, but is transmissible to both shoulders, arms, and trunk and to both lower extremities.

8. Pathological impulses have, in my experience, been definitely connected with a large number of phenomena.

NOTES

1. It has been routine practice with me now for some time to block off the throat distress at intervals after removal of tonsils. The relief that it gives is very complete and the gratitude of patients for such relief is unbounded.

2. and likewise 3. are among my records but unreported.

4. This case was in the practice of Dr. English, of Palmetto, Fla. A diagnosis of cancer of the uterus with metastases had been made something like a year before. At the first time I saw her some two months before death, she was confined to bed, and kept more or less continuously under the influence of opiates. After it was discovered that cocainizing the left nasal ganglion relieved her pain, she preferred that to opiates and as a result I saw her almost daily till she became moribund. At first I used eight per cent. cocaine for blocking the nasal ganglion, but later used four per cent. butyn with adrenalin. The butyn in that strength was not quite so quick and the results not quite so complete in action as the cocaine. In this connection I may mention another case which came under observation. At the time I saw her she had had a hysterectomy eight months ago for cancer and now she had a tumor mass just above the left clavicle about the size of an egg, hard, sore to the touch, and radiating pain down the shoulder, arm and chest. It was found that the pain could be completely blocked off from the left nasal ganglion, leaving only a slight residue of soreness. This was repeated on three several occasions after which she was referred to Dr. Helms of Tampa, who removed the mass and made a diagnosis of sarcoma. These are the only two cases of malignancy in which I have done any nerve blocking.

True Dermoid Cyst of the Anterior Wall of the Rectum*

JOSEPH F. SAPHIR, M.D.

New York

On December 4, 1923, Dr. L. A. asked me to see Mrs. I. S., thirty-eight years of age, married seventeen years, who had been delivered of her sixth child, four days before I was called. She was delivered in a sanitarium, and the object of my visit was to determine the advisability or necessity for the removal of the patient to a general hospital for better attention and pathological observation. Her history, copied from a statement given to me at the sanitarium, was as follows:

"Mrs. S. was delivered on November 30, 1923. While the child's head was extracted by low forceps, she expelled by rectum a large hair ball with a fatty exudate resembling vernix caseosa. She denied having swallowed any hair so I made a tentative diagnosis of ruptured dermoid cyst. She had complained of gas pains, which we tried to relieve by high colonic irrigations. After the last two irrigations, she had passed blood, which seemed to come from the colon. Temperature, pulse, respiration, and lochia were normal, uterus undergoing involution. Patient was highly hysterical, and I had advised removal to a general hospital, where she could be kept under observation, and the pathological condition ascertained."

Examination of the expelled mass revealed a mass of matted blond hair, the size of a large hen's egg, the hair being very fine, and the strands from six to eight cm. in length, and matted together with a caseous material. The hair was distinctly blond in contradistinction to the dark hair of the patient, ruling out the swallowing of her own hair, which is not uncommon in mental defectives and in psychoneurotics.

Proctoscopic examination revealed a large ulcerated area beginning about two and a half inches above the anal opening on the anterior wall of the rectum, and extending for about two inches transversely involving about one half the circumference of the bowel, and was filled with granulations and clotted blood. Some oozing of fresh blood was also present.

The upper lip of the ruptured cyst was extremely edematous; so much so as to be in direct contact with the posterior wall of the bowel, and interfering with the evacuation or expulsion of fecal matter, which incidentally permitted fermentation with gas production, and abdominal distention, and inter-

*Presented at the annual meeting of the American Proctologic Society, held in New York, June, 1924.

fered with the proper insertion of the irrigating tube for the relief of the accumulated fecal matter and gas. Insertion of the irrigating tube into the rectal canal was made impossible, beyond the location of the ruptured cyst, and when the tube was inserted, entered the cyst cavity, breaking off some of the granulations and caused bleeding, which the doctor reported as coming from the colon.

A diagnosis of a ruptured dermoid cyst of the anterior wall of the rectum was made, and after having passed a rectal tube, with the aid of a proctoscope, beyond the edematous lip of the sac wall, the bowel was thoroughly cleansed of all accumulated gas and fecal matter. Astringent irrigations were then ordered to check the bleeding.

The woman was very pale and anemic, weak, and her resistance low; operative intervention was contraindicated, so I decided to postpone any possible surgical procedures until her condition had so improved as to make her a fairly good operative risk. Three days later, I saw the patient again. The bleeding from her rectum had been checked, her bowels were moving daily with the aid of mild cathartics, and her astringent irrigations were continued twice daily.

To corroborate my diagnosis of a true dermoid cyst of the anterior wall of the rectum, and to eliminate the possibility of its being an ovarian cyst which had worked its way through the anterior wall of the rectum and then ruptured, I advised a thorough gynecological examination, and one week later, December 12th, Dr. Arnold Sturmdorf was called in, who reported, after a complete gynecological examination, that the tubes, ovaries, and adnexa were perfectly normal and that there were no signs of any connection between the pelvic organs and this dermoid cyst.

December 14th, another proctological examination was made, when I found the rectal wall clean, no bleeding, the ruptured sac was much contracted, only a small opening remaining, through which a few strands of fine hair presented themselves, and a few drops of pus were noticed. I removed the strands of hair, and somewhat dilated the opening of the remaining sac to permit better drainage, but decided that although excision of the entire cyst wall would be necessary to get a complete cure, the cystic cavity was so high up that I thought it better to continue for the time being the rectal irrigations, and keep the sac open, since the woman's enfeebled condition would not permit any operative intervention.

December 22d, proctoscopic examination showed a small opening exuding a drop of pus, which opening I enlarged or dilated by insertion of a Kelly clamp and spreading the blades apart.

January 3, 1924, she called to see me at my office, when I advised continuation of the rectal irrigations with a saline solution, and to wait until she had some manifestations that would necessitate operation. I advised against operation for the present, due to the fact that an extensive operation would be necessary. The sac was situated too high up for a perineal resection of the bowel, and the patient was too dangerous a risk for any extensive abdominal work. Besides, she had a family of six children to look after, which she could well attend to in her present condition. I advised her to see me once a week for the purpose of keeping the sac open to permit the pus to drain into the rectal cavity, and by means of irrigations to wash the pus away,—and told her that we would operate only when the sac closed and symptoms of pus absorption took place; that is, when it became absolutely necessary.

January 10th, the patient called to see me. She appeared better, had gained in weight, had better color, and was feeling well and attending to all her household duties, and taking care of her children. The sac opening was very small, and I dilated it. I again advised her of the importance of having herself looked after once a week.

March 13th, two months and two days later, she called to see me, when she gave me a history of having felt very well and thought that she might postpone her visit, and two weeks after she had seen me, temperature and headaches had developed. She called her family doctor, who treated her for the grippe for a week from January 23d to 30th, and on January 30th, she had a sudden high temperature and a chill and severe cramps in the left side. She was taken to the Mt. Sinai Hospital January 30th, and was operated upon February 12th, thirteen days later. She remained in the hospital for three weeks, and was sent home feeling better. She then went to see Dr. Sturmdorf, who referred her back to me.

March 12th, one month after her operation, she called to see me and complained of now having a discharge of pus from the vagina. A vaginal examination showed that an incision had been made in the posterior vaginal fornix, from which there was a pus discharge. Apparently, when taken to the hospital, the true condition was overlooked, and a diagnosis of a pelvic abscess had been made, and an incision into the pouch of Douglas was all that had been made. Examination of the rectum showed a small opening into the cystic sac, but still discharging pus. I again advised her against a radical operation, and she now sees me regularly once a week. I continue the rectal saline irrigations, and continue to keep the cyst cavity from closing. She is in good shape now, has no pains or aches, has greatly improved in color, health and strength, and has gained over thirty pounds in weight.

In looking up the literature I find this to be a rare condition, which is but one of the reasons I have to offer for presenting this case for your consideration.

Arnold Sturmdorf (1) attributes this condition to failure of embryonal occlusion of the neuroenteric canal. There may be simple pilonidal cutaneous (dermoid cysts) or postrectal dermoid pockets communicating with the rectum, or a fistula may lead from the skin to the mucosa of the bowel.

The variety we have here is the postrectal type communicating with an epithelium lined pocket behind the rectum.

A retrorectal dermoid may become infected and rupture into the rectum, discharging pus and debris for months and years. A sinus or opening in the posterior rectal region discharging pus, hair and débris would lead to a diagnosis, but the surgeon rarely sees the case in this condition. He finds an opening leading to a suppurating cavity, or the pa-

tient complains of periodical discharge of pus from the bowel, the source of which may not at the time be apparent, owing to the intermittent closure of the fistulous opening. Simple incision and drainage or cauterization cannot effect a cure. The cavity is lined with epithelial cells presenting an organic secreting tissue curable only by radical extirpation.

C. B. Kelsey cites A. Danzell (2), who reported a case in a woman aged twenty-five years, in whom a lock of brown hair, the size of a finger protruded from the anus occasionally after defecation. In the front well of the rectum about two and a half inches from the anus, a hard tumor could be felt about the size of a small apple. This was extirpated by introducing the whole hand into the rectum, death following some months later from peritonitis. The hair growing from this tumor was twelve to eighteen cm. long, the tumor itself when extirpated measured four and five tenths cm. long, four cm. in breadth, and three and five tenths cm. thick. The microscope revealed the usual cyst wall and its contents.

Perrin (3) gives an account of three cases of these tumors.

Hodges of Boston (4) described the condition under the name of pilonidal sinus, pilus, a hair, and nidus, a nest. This affection is simply a ball of hair and dirt in a sinus between the anus and the tip of the coccyx. The sinus is a deep symmetrical conical dimple of congenital origin, representing imperfect union of the lateral halves of the body, involving the integument alone, in which as life advances, short hairs and particles of dirt accumulate. These by irritation cause a purulent discharge from a fistulous opening of the cavity and when the case comes under observation may be mistaken for a fistula in ano.

Van Duyse (5) reports the history of a case of labor during which a rectal dermoid was expelled. The dermoid contained a cerebral vesicle, a rudimentary eye, a canine tooth, and a piece of bone.

Pennington (6) asserts that there are many hypotheses for the origin of dermoid cystic tumors. The simple variety as explained by the inclusion theory of Verneuil, e. g., during development a portion of the integument is nipped off, and keeps on growing, though ensconced in the neighboring tissues. The complex growths with bone, cartilage, teeth, etc., are accounted for by Roux's blastodermic hypothesis; e. g., the ovum divides into the primary blastoderms, and if for some reason, the normal development of the latter is interfered with, each may give rise to a smaller embryo, an imperfect embryo, or a complex dermoid (teratoma) with portions of brain, mammary gland, intestine, etc.

True rectal dermoids are much less frequent than similar growths located behind the gut. Nearly all of the recorded examples of rectal dermoids have been found in women, and this gives some support to the former suggestion that they arise in the ovary and erode their way into the rectum (Bland-Sutton).

Mummery (7) reports the removal of a dermoid from behind the rectum of a girl of sixteen with black hair, but a lock of bright red hair was found in the cyst.

Clutton (8) removed an oval tumor with a double pedicle, now in the St. Thomas Hospital Museum, London, from the sigmoid flexure of a girl of sixteen. The pedicle was attached to the wall of the sigmoid and the tumor hung loose in the lumen. The tumor is solid, and is covered with skin and hair. During life the hair grew very long and hung out of the patient's anus, where it had to be cut off periodically.

Tuttle (9) emphasizes the necessity of distinguishing true dermoids of the rectum and those which develop in its walls, the rectovaginal septum, and retrorectal space. Those that originate outside of the rectum may break through into it by ulceration or rupture, and protrude in a polypoid manner into the gut, giving the impression of a growth originating within the organ. He reports (10) a case of a girl of ten with a discharge of blood and pus with stool, and during defecation, a matted mass of tufted hair protruded from her anus. Careful examination showed a rent in the wall of the rectum with the ulcerated edges, through which the tumor protruded. This was a case of dermoid cyst which originated outside the rectal wall, and was forced by straining and abdominal pressure.

Port (11) reports a similar case in a girl of sixteen, from whom he removed a tumor apparently originating in the rectum.

Bazel (12) reports the case of a woman who noticed protrusion of hair from the anus during defecation. He removed a tumor the size of an orange attached by a pedicle to the posterior wall of the rectum about two and a half inches above the anus.

Van Duyse (13) reported the case of a woman of thirty-two, who passed spontaneously from her rectum during labor a tumor which proved to be a dermoid cyst containing a rudimentary eye.

From the above reports of cases, we must admit that although true dermoid cysts are rare, we frequently find tumors of this type in the walls of the gut or attached to their outer surface. These walls may be ruptured, especially during labor, and the tumor be brought down within the gut or delivered through the anus.

The etiology is similar to that of dermoid cysts in other parts of the body, nearly always found in the female sex. They are congenital from the number of cases found in young children. They are not discovered until later in life, when the tumor becomes larger, and causes obstruction to the passage of the fetal head, or to a large hard fecal defecation.

I am presenting this case not only for its rarity, but because I want to get your unbiased expression of opinion as to what you would have done in a case of this kind. Have I done the right thing by this patient, and would you advise the radical operation in spite of the risk and danger entailed, taking also into consideration the responsibilities and the family obligations of this woman?

I should be glad to present this patient for examination at my office to those who are interested.

Peritonsillar Abscess with Complicating Edema of the Glottis*

SIMON STEIN, M.D.
New York,

Peritonsillar abscess is not an unusual occurrence, in fact is so common that the practitioner as a rule has no hesitancy in treating this condition as part of his routine work. The case I am reporting is just such a one with a complication that had serious possibilities and I wish to place it on record for that reason.

Case.—Mrs. G., aged thirty, was brought to me with a right peritonsillar abscess, by Dr. B. Herschkowitz, who had seen the patient only an hour before, and recognizing the case as one not of the ordinary type, asked my cooperation in treating her. Examination showed the posterior pillar of the right tonsil to be greatly enlarged, boggy and bulging. The anterior pillar and soft palate were reddened and slightly thickened. The tonsil was pushed forward a little. The superficial tissues over the bulging area were infiltrated with a half per cent. novocaine solution. An incision was then made in the posterior pillar, and a large clamp inserted, extending it slightly backward and downward, until I felt myself going into a large cavity, from which there was a gush of white pus, in all about two ounces. A large opening was obtained by withdrawing the clamp in the open position.

The patient was then sent home, given a mouth wash and instructed to irrigate the involved area in order to get rid of the detritus and give free drainage. She was doing well for that day but at night complained of a choking feeling. Dr. Herschkowitz was called in the morning and when he got there the patient had brought up about three ounces of pus and was feeling better. He found that the boggy swelling of the posterior pillar had extended downward somewhat, but the condition seemed satisfactory and the incision was wide open. There had apparently been a collection of pus below, which was discharged through the incision that had been made. About eight hours later the doctor was called again, the patient complaining of difficulty in breathing. This time he saw that the inflammation had extended to the epiglottis, and the patient was brought down to me.

Examination showed that the inflammatory swelling had extended down to the base of the tongue, and from there, across the base of the tongue, and involving the epiglottis, was a sort of cystic edema of the superficial tissues, as if a solution had been injected producing a bleblike formation. The entire epiglottis was involved, and extended to the false cords and arytenoids. The true cords were just glimpsed, but had not yet been involved. The incision that had been made was found patent and leading into a large cavity, with no free pus, just a boggy mass.

With a fine pointed paracentesis knife, I punctured the edematous area, obtaining a clear straw colored fluid. The patient was then given an adrenalin spray and cold packs to the neck. She was watched very carefully during the night, but there were no further complications, and in the morning the edema had disappeared and the patient was feeling well. From then on recovery was uneventful and three weeks later the tonsils were removed under local anesthesia. The only thing of note at this time was the considerable thickening of the posterior pillar which stood out as if in tension. This was not seen when the tonsil was *in situ*.

One wonders, considering the anatomical structure of the pharynx, that more of these complications do not occur than are reported. The pharynx is made up essentially of the large constrictor muscles, which are laid one over the other and loosely invested by a common fascia, and just beyond them we have the great vessels with their loose packing of areolar tissue extending down the neck to the mediastinum. Excellent pathways for infection.

Several interesting complications have been reported. Richards reports a case which started as a peritonsillar abscess and extended down to the second ring of the trachea. The patient ceased breathing necessitating a hurried tracheotomy, and then it was found that the abscess extended down alongside the trachea. Then there are reports of abscesses extending to the mediastinum, and those involving the great vessels, with severe hemorrhages.

The case reported here was apparently an involvement of the palatopharyngeous and superior constrictor muscles, the condition of surrounding edema being similar to the edema surrounding any inflammatory area.

In conclusion, I wish to emphasize the importance

*Read before meeting of Beth Israel Hospital Alumni Association, New York City.

and danger of inflammation in the tissues surrounding the tonsils, because of the important structures in the immediate vicinity, and the easy pathways by which these inflammations can spread. Therefore peritonsillar inflammation should not be regarded lightly, even though so many of these inflammations run the course of any apparently minor surgical condition.

A New Stopcock for Direct Blood Transfusion

ANDREW A. EGGSTON, M.D.
and JOHN A. MORAN
New York

Blood transfusions have become recognized as a valuable and essential therapeutic procedure in a great many conditions and diseases. There are, however, several phases which require further consideration. Particular reference is made to the need of additional information regarding blood types and the nonspecific reactions which follow transfusions and further improvement in technic. A great many posttransfusion reactions are undoubtedly due to technical errors in the performance of this delicate operation. Any one with an extensive blood transfusion experience will be led to conclude that a great many reactions can be entirely avoided, or greatly reduced in severity, as any one of the procedures now popularized become mastered by the operator. At present there are several ways of delivering unaltered blood (blood without the admixture of anticoagulent substances), in a more or less rapid and satisfactory manner. However, these methods are further subject to improved modifications. It is with this idea in mind that we wish to describe a new apparatus, or stopcock, for direct blood transfusion which in our hands has superseded all others.

DESCRIPTION OF APPARATUS

The apparatus consists of a four way stopcock (Fig. 1-a), which is composed of a plug having two oblique bores extending from both ends at an obtuse angle toward the centre with the outlets of the canals upon opposite sides of the plug (Fig. 2). When the plug is in position the outlets of these canals connect directly to the lateral outlets of the stopcock to which is attached the rubber tubing leading to patient and donor (Fig. 3-a). The canals do not connect in the centre of the plug, thus allowing two currents of fluid to pass through the stopcock in opposite directions simultaneously without admixture. In order to reduce the distance through which the stopcock has to be turned in shifting the outlets from left to right, or right to left, grooves are made transversely upon the surface of the plug which extends half the distance between the two openings. The grooves run in the same direction from their respective canals but do not connect (Fig. 2-a). This reduces the turn of the stopcock from a semicircle to a quadrant. While these grooves are not absolutely essential they are advantageous because of this decreased motion. The terminal ends of both canals are ground to fit Record syringes. In order to prevent the separation of the two portions of the stopcock during the manipulation there is placed on the distal end of the plug a washer (Fig. 3-b), which is held in position by a screw nut (Fig. 3-c). The latter is similar in appearance to the proximal end of the plug. The stopcock is mounted upon a metal rod (Fig. 3-d), which is fastened to a large clamp (Fig. 3-e) by means of a setscrew. The setscrew allows the stopcock to be securely fastened in various positions as the physical conditions of the operation may demand.

THE TECHNIC OF BLOOD TRANSFUSION

1. Two beds, stretchers, or operating tables, are arranged parallel and about eight or ten inches apart. Both the patient and donor should lie in recumbent positions, and as near to the edge of the bed as possible. The character of the veins of both, recipient and donor, determine to a great degree their respective positions. They may be placed side by side with their heads in the same direction, or they may be placed in the opposite direction. Careful study of the most available veins should be made before the operation is begun.

2. A board, twenty by ten inches, (Fig. 1-6), covered by a thin rubber sheeting, is placed between the recipient and donor. The board should be adjusted so that easy connections can be obtained by means of the short rubber tubing leads from the stopcock to the veins of donor and patient at the bends of their elbows.

3. The recipient's and donor's arms are sterilized from shoulder to wrist with three per cent. iodine followed by alcohol. Sterile towels and half sheets are placed around all areas coming in contact with the operators, including the hands of the donor and recipient.

4. A small table, draped to receive the sterile instruments and materials, should be available. The essential materials consist of several 18 French rubber catheters which have been cut into pieces six inches long, three or four 20 c. c. Record syringes, sterile saline, two tourniquets, the stopcock, connecting tips, transfusion needles and petrolatum. Instruments for exposing veins may be on hand but are rarely necessary.

5. As the patient is being prepared the operators scrub their hands as for surgical operation. The stopcock of the apparatus is well lubricated with petrolatum before it is assembled. Syringe B is

filled with saline solution. Syringe A contains just enough saline to expel all air. Several extra syringes should be kept on hand in case of emergency.

6. The apparatus is fastened to the board between the patients and the syringes inserted firmly

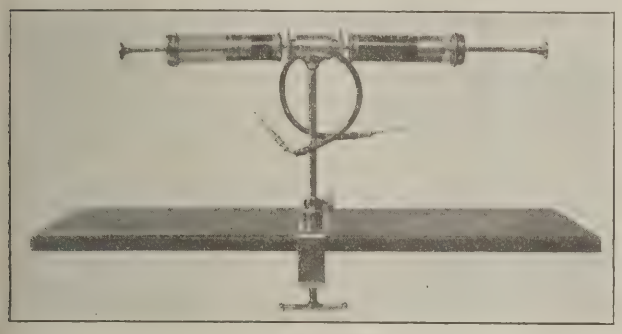

Fig. 1.—Four way stopcock apparatus.

in their respective canals. All air in the tubing is replaced by saline solution. The canals of the apparatus should be so arranged that A connects with the donor and B with the patient. Care should here again be taken to see if the rubber leads reach the position where the needles are to be inserted into the veins (Fig. 4).

7. The tourniquet is applied to the arm of the patient. The needle, gauge 15, is carefully inserted into the recipient's vein and the trocar removed. The point of the needle should protrude for some distance into the lumen of the vein. Connection is now made from the apparatus to the needle and tourniquet is released. Five or ten c.c. of saline is injected by syringe B to determine if complete entry into the canal of the vein has been accomplished. Do not proceed until this connection is entirely satisfactory. The saline solution must enter with slight pressure and there must be no infiltration of the patient's arm. It may be necessary to

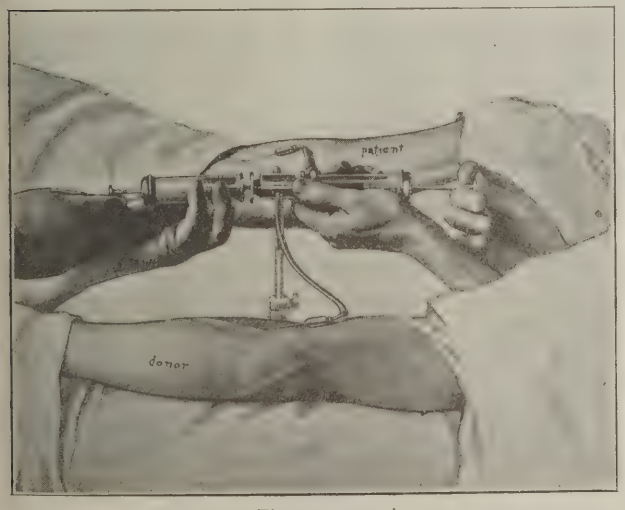

Fig. 4.—The apparatus in use.

maintain some pressure on plunger of syringe B in order to prevent patient's blood from entering connections. The patient is instructed to lie quietly. If saline is forced through the connection to the patient's circulation some time can elapse without interfering with the procedure. This allows the operator considerable time and care to enter the vein of the donor.

8. The tourniquet is tightened upon the arm of the donor and the pulse taken to insure free arterial circulation. Needle, gauge 11, is inserted into a large vein at the bend of elbow of the donor. If practicable the needle had better be inserted downward toward donor's hand, this being the reversed position of the needle in the recipient. It is absolutely essential to get a gush of blood from the donor's vein when the trocar has been removed. The most important requisite for a perfect direct transfusion is an unobstructed forceful flow of blood from the donor. Any interference whatever with this flow interferes with the success of any direct method of transfusion, so that it is most imperative that both the vein of the recipient and the donor are properly entered by needles of sufficient calibre. The tourniquet upon the donor's arm is not released and it may be necessary to have the donor open and close his fist frequently to produce more rapid bleeding.

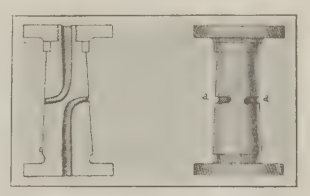

Fig. 2.—Internal bores and mechanism.

9. As soon as the insert of the rubber lead to the stopcock is connected with the needle of the donor the blood rushes into syringe A. While this syringe is filling the remaining saline solution in syringe B is injected into the patient. When syringe A is full of blood syringe B is empty of saline, and the stopcock is turned by the operator of syringe A, by holding the wheel of the stopcock and syringe so that both turn simultaneously. This shifts the canals in a position so that A is in B's position, and B in A's. The blood in syringe A is injected into patient while syringe B is drawing blood from the donor. Pressure toward the apparatus must be applied upon the barrels of the syringes while they are drawing blood, thereby preventing the entrance of air. This alternate drawing and injection of blood by syringes A and B is continued until the desired quantity of blood had been given. Twenty-five syringes containing twenty c.c. each are necessary to deliver five hundred c.c. of blood; fifty syringes full for one thousand c.c. Any amount may thus be easily determined. It is better to have some one assigned for the purpose of keeping accurate count of the number of times each syringe has been filled and emptied. If no assistant is available to use the distal syringe, this canal may be plugged, thus allowing the use of the stopcock by one operator. The distal end of the stopcock may also be used for the simultaneous injection of saline, or immune serum.

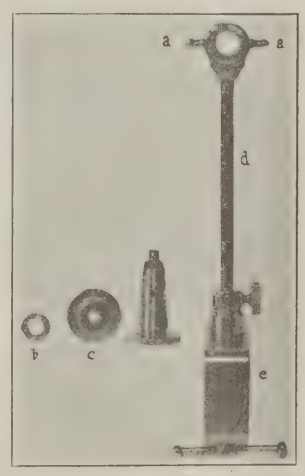

Fig. 3.—Separate parts of the apparatus.

10. When enough blood has been given the donor's tourniquet is released and the needles of both, the patient and donor, are removed. The arms are bandaged firmly to prevent extravasation.

11. The apparatus is carefully cleansed with soap, water and alcohol, making sure that all the canals are entirely free of blood. It is well to apply vaseline to all the parts to prevent tarnishing.

ADVANTAGES

1. Rapid delivery of a large quantity of blood with an uninterrupted stream.
2. Decreased number of reactions.
3. Accurate measurement.
4. Simplicity of construction.
5. Can be manipulated with patient and donor in various positions.
6. Can be used simultaneously for the injection of immune serum or saline solution.
7. Adapted to use by either one or two operators.
8. It is inexpensive and can be readily cleansed and sterilized.

653 Park Avenue.

Venipuncture in Therapy

C. S. DANZER, M.D.

Brooklyn, N. Y.

Our forefathers in medicine already knew of the great benefits to be derived from bloodletting. The recklessness of its application, however, soon led to its abandonment. It was either because improperly selected cases were treated or because the amounts of blood removed were so excessive that the method fell into disrepute. Nevertheless, in properly selected cases, the withdrawal of moderate amounts of blood at certain intervals is followed by remarkably good results.

The writer has employed venipuncture—removing from seventy-five to two hundred c. c. of blood at intervals of a few weeks to several months—and has obtained such encouraging results in certain cases that it seemed worth while to devise a simple and efficient technic for the carrying out of this procedure.

Originally a single twenty c. c. syringe (Record) was used. The technic consisted simply in disconnecting the syringe from the needle when the former was filled, emptying the blood, washing the syringe, and connecting it to the needle in the vein again; now blood was drawn into the syringe once more. By this time the blood had coagulated in the needle or the latter had slipped out of the vein. It was therefore necessary to start anew, puncture the vein again and repeat the whole procedure. This meant that the patient had to be hurt considerably or the procedure prematurely terminated with consequent failure of the method.

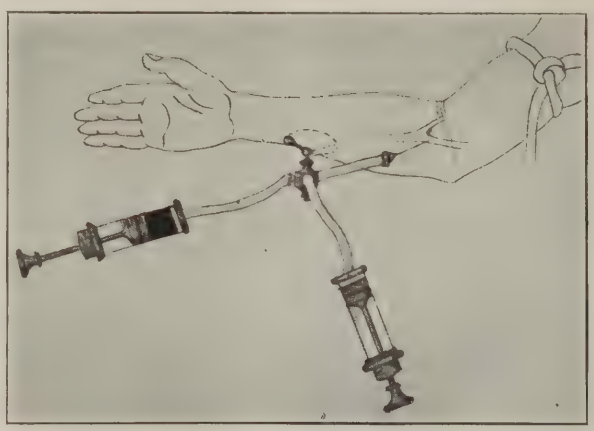

Fig. 1.—Showing connection of syringes in venipuncture.

The scheme which we have finally worked out and which we now use is as follows: Two twenty c. c. Record or Luer syringes are connected by means of rubber tubing with two ends of a three way stopcock. The third end of the latter is connected by a piece of tubing to the needle, the lumen of which must not be too narrow. Now the vein is punctured in the usual way and one syringe is filled. The stopcock is turned so that the other syringe is in series with the needle, and the blood is aspirated into the second syringe. Meanwhile an assistant disconnects the first syringe, empties the blood into a basin of warm water, washes the syringe, and reconnects it. The stopcock is turned back to its original position, so that syringe number one is connected with the needle and blood is again aspirated. Meanwhile syringe number two is emptied of its blood, washed and connected again (Fig. 1).

In this way a fairly large quantity of blood can be removed in a few minutes, i. e., before blood begins to clot in the needle. There is practically no discomfort to the patient except for an occasional slight feeling of giddiness following the removal of blood. To prevent this we have had patients drink a tumbler of water immediately after venipuncture in order to favor the rapid restoration of the blood volume.

We have applied this method to office practice, performing it on a number of patients in the course of an office hour, as well as in the outpatient clinic and the hospital, and have found it generally satisfactory.

The effects of the venipuncture as we carry it out —where 100 to 250 c. c. of blood are removed—are as follows: The patients usually experience a sense of well being soon afterwards; frequently saying that they feel lighter. The blood pressure usually remains unchanged; sometimes there is a slight rise, at other times a fall in systolic pressure.

Patients with cardiac or renal edemas resisting the usual forms of medication, soon lost them if the treatment was preceded by a venipuncture. In the case of edematous patients, the customary administration of water following venipuncture is omitted.

The conditions treated by venipuncture were varied. Cases of cardiac decompensation, especially those with attacks of nocturnal dyspnea (cardiac asthma or Cheyne-Stokes attacks) have reacted miraculously. Congested livers which had previously resisted therapy now would recede quite promptly and the general circulatory condition would improve. Diuresis was frequently stimulated and transudates were quickly resorbed.

Arteriosclerotics, especially the pale and cachectic ones, have bloomed up under this treatment. They became more cheerful and their complexions improved. It seemed as though the bone marrow was stimulated to the formation of new blood. The blood pressure was not usually lowered, in some cases it even rose. The headaches, dizziness and the hot flashes common to women at the menopause frequently lessened. It must be emphasized that we have not restricted this procedure to hypertensive arteriosclerotics. The object in mind was not the reduction in blood pressure.

In a few cases of angina pectoris the patients seemed to do well after repeated venipunctures. In one case of arteriosclerotic auricular fibrillation, the fibrillation stopped and the patient has done very well under the usual treatment ever since the withdrawal of blood from the vein.

It is probable that the improvement in arteriosclerosis occurs because a certain amount of an unknown toxin is removed from the bloodstream and the rest is diluted by the compensatory hydremia following the removal of blood. That arteriosclerosis may originate from some toxin circulating in the blood stream needs no argument. One need only recall the attractive theory of Huchard (1) in this connection. This clinical master considered arteriosclerosis as an intoxication from start to finish.

Another factor which may account for the improvement in this condition is the fall in blood viscosity. This amounts to seventeen per cent. after moderate bloodletting—according to Burwinkel (2) of Nauheim. Because of this, a thinner blood may trickle through narrowed vessels.

Patients with chronic nephritis, especially those with suburemic symptoms, have shown improvement when treated in this way. Their weakness, pallor, anorexia and nausea were oftentimes strikingly benefited. Now thorough digitalization of the heart would be successful in averting an impending uremia. I have observed such an instance in a woman who had had a suppression of urine for four days and who was tided over in this way, but she eventually died in her last uremic attack six months later.

Two stubborn cases of urticaria have reacted beautifully after withdrawal of sixty c. c. of blood. The effect was immediate. On the day following, in order to enhance the therapeutic effect, the serum was reinjected into the veins. This reinjection of autoserum is the mildest form of protein therapy.

Chlorotics and patients suffering from secondary anemias have reacted satisfactorily after repeated venipunctures.

Finally we should like to mention eclampsia. This condition has responded to treatment by venipuncture followed by glucose infusions. These were easily carried out with our method. Our own experience has been limited to cases of postpartum eclampsia. Here medical consultation was requested because the condition seemed grave even after the uterus was emptied.

This is a brief summary of our experiences with the class of cases treated by venipuncture. They are rather encouraging and we believe the method is worthy of more general application.

It may be worth while to quote before concluding Hufeland (3) who said: "It seems probable that the reason for the striking increase in the incidence of cardiovascular diseases in the past twenty years lies chiefly in the neglect of therapeutic bloodletting during this time." This suggests the idea that venipuncture performed in cases of mild or incipient arteriosclerotic disease might be used prophylactically to prevent the more serious forms of vascular heart or kidney disease.

SUMMARY.

A simple efficient method of bloodletting is described. It is hardly unpleasant to the patient. Quantities of blood varying from fifty to a few hundred cubic centimetres are removed at intervals of a few weeks or months. Good results have been obtained in arteriosclerosis, chronic nephritis, cardiac decompensation especially when associated with cardiac asthma, chlorosis and secondary anemia, urticaria and eclampsia.

The author's references will appear in his reprints.

Ectopia of the Urinary Bladder in an Infant

J. EPSTEIN, M.D.
New York

Exstrophy or ectopia of the urinary bladder is a rare congenital malformation. This distressing deformity is the result of an incomplete closure of the ventral body wall and a failure of the normal formation of the urogenital system.

At the dawn of embryonal development, after the three primary germ layers have formed, the lateral parts of the mesoderm split transversely into two equal layers; the outer one unites with the ectoderm to form the somatopleure, and the inner unites with the endoderm to form the splanchnopleure. The body then begins to assume some shape and form and from the flat embryonal structures which lie in the embryonal area an infolding begins at the periphery to form the framework. This infolding continues until there are formed two tubes, one within the other. The inner tube, made up of the splanchnopleure, gives rise to the alimentary canal while the outer tube which is made up of the somatopleure forms the body wall. Union of the outer embryonal tube

which makes up the body frame takes place along the median line on its ventral surface. The wall of the body cavity is thus joined or seamed together along the median line of the thorax and abdomen.

This line of junction of the abdominal wall is structurally of less resistance than the rest of the body and is therefore occasionally marked by umbilical and epigastric hernias or by a diastasis of the recti muscles. Imperfect development of the body wall or a failure of the proper closure of the body cavities may occur at the line of junction and give rise to slits and clefts of various degrees. A cleft in the maxillary region causes harelip and cleft palate. A fissure may occur along the sternum and divide the thorax in two equal parts. A cleft in the cardiac region may cause an ectopia cordis or give rise to a pulmonary hernia. A slit in the lower abdomen may occur and expose the abdominal or pelvic viscera. In most cases of abdominal clefts, the process extends to the organs lying behind the wall. A cleft in the hypogastric region usually involves the bladder, urethra and the pelvic girdle, so that the posterior wall of the bladder protrudes through the abdominal slit and the urethra is open on its dorsal surface, exposing the grooved floor.

In some cases it is possible that the opening in the abdomen is secondary to a cleft in the bladder, thus providing an easy external outlet for the urinary flow. The edges of the bladder are then fused with the opening in the abdominal wall, making the skin continuous with the inner lining of the bladder. It is, however, always difficult to tell whether the primary malformation is in the bladder or in the abdominal wall as in the case reported below.

Fig. 1.—Ectopia of the bladder, epispadias, bilateral inguinal hernia, in a baby five months old.

Case—P. B., a boy five months of age. Pregnancy, birth and later general development were normal. He was the second child of young, healthy, Polish parents. The first child was well in every way. There was no history of chronic disease or malformation in either family. No consanguinity in the parents. The child was born with a cleft in the lower abdominal region through which the posterior wall of the bladder protuded and the kidneys emptied themselves.

On examination there was seen a square, red, corrugated, fleshy mass which occupied the space between the umbilicus and the symphysis pubis, as shown in Fig. 1. It was three by four cm. in diameter and extended well above the surface of the abdomen. From the lower part of the dislocated bladder the urine welled up, keeping the parts moist and excoriated. The penis, except for the glans, was rudimentary and presented a condition of complete epispadias. There was a bilateral inguinal hernia. The testicles were in the normal position. The rest of the physical examination showed a healthy, well developed child.

DIAGNOSIS

The diagnosis of exstrophy of the bladder is comparatively simple. It mostly occurs in male children without regard to race or age of the parents. The abdominal cleft with the protuding red mass which is constantly moist, the epispadias or the cleft in the clitoris and labia, all point to the proper diagnosis. As a result of intraabdominal pressure and the cut in the anterior wall of the bladder, the exposed organ is everted and protudes above the surface of the abdominal wall. The condition predisposes the child to infection of the urinary and intestinal tracts. Many die in infancy, some live to childhood, but few reach adult life.

Complete absence of the bladder, or a reduplication of the bladder or a partition of the bladder may occur. Some of these malformations are difficult of diagnosis and incompatible with life.

TREATMENT

The treatment is mainly surgical. It consists in a plastic operation of the bladder and the abdominal wall. The bladder is either repaired or reconstructed and the slit in the abdomen is covered with healthy flaps. The ureters may be transplanted in the rectum, making that part of the gut serve both as a bladder and as an intestine.

Medically there is nothing to be done except to keep the part clean in order to prevent infection of the bladder and the kidneys, and to keep the skin from excoriation.

The prognosis is poor. In most cases the condition is beyond operative repair. The child usually exists for a shorter or longer time until some intercurrent disease relieves it of its troubles.

213 East Broadway.

Intravenous Bismuth Treatment.—Fritz Mras (*Wiener klinische Wochenschrift,* July 17, 1924) found that the intravenous injection of bismuth in the form of sodium tribismuthyltartrate, giving ten c.c. of a 0.5 per cent. solution three times weekly gives results equally as good as those obtained with the larger doses given intramuscularly and that these injections are well tolerated. The considerably less frequent occurrence and diminished intensity of the disturbances of sedimentation are noteworthy. The results obtained in twenty-three patients are very encouraging, but a final opinion cannot be given.

Practical Therapeutics

RESISTANCE OR TOLERANCE OF THE GONOCOCCUS TO GERMICIDES IN RELATION TO ANTIGONORRHEAL THERAPY

THOMAS V. WILLIAMSON, M.D.
Norfolk, Va.

Since the publication of the article on The Resistance or Fastness of the Gonococcus to Germicides (1), in which the contention was advanced that this organism possesses an inherent ability to set up a defense against the solutions employed to destroy it, so that the effect of these germicides might be either greatly inhibited or else rendered practically useless, added experience and extended clinical observation seem to indicate that the point was well taken. In the meantime, Young and Miss Hill, at the Brady Clinic, note that, in laboratory experiments, the colon bacillus becomes unduly resistant to mercurochrome when it is continuously subjected to dilute solutions of that preparation. (2) Von Lackum and Hager of the Mayo Clinic advocate the alternate use of mercurochrome with the silver derivatives in the treatment of acute gonorrhea on the ground that the gonococcus becomes recalcitrant to the germicidal authority of either one when constantly employed for any great length of time. (3) Roblee draws a more hopeful picture of the future management of gonorrhea and styles, as specific, the treatment based on the recognition of this phenomenon of germicidal resistance (4).

The process of reasoning which led up to the original communication on this subject was as follows: primary gonorrhea, within the male urethra during the early initial stage, is a very simple disease. It is, then, a superficial, localized, readily accessible implantation upon the mucous membrane of the outer urethra. There is nothing complex about it, and it seems that a germicide applied to this superficial, inextensive inflammatory area, in a concentration known to be quickly lethal to the gonococcus, should have an absolutely paralyzing effect upon that pathogerm. But no chemical has been introduced which will uniformly abort gonorrhea, nor has any yet been found which will produce a systematically satisfactory result in the early acute course of the disease after the period for the abortive treatment has passed.

When using one particular germicide in a series of cases, the following variations are likely to be noticed: in some of the infections, the discharge and acute symptoms are combated like magic, while, in the remaining cases, there is either no improvement at all, or else the inflammatory condition becomes more intensely aggravated for the time being. It is also by no means unusual to observe that an infection, which responded beautifully to treatment at first, in the course of a few days, will break out of therapeutic bounds and take on an apparently unwarranted activity which is startling both as to virulence of symptoms and rapidity of extension.

There must be some scientific explanation of this therapeutic incompetency and variability on the part of remedial agents employed locally against the gonococcus. The profession has found that it is absolutely unable to prevent many of these infections, which are simple in the beginning, from becoming complex and deep seated and which, together with unfortunate sequelæ and secondary manifestations, exhibit an indefinite persistence. The only explanation which fits the facts in the case is that this puzzling occurrence is due to an immunity or resistance which the gonococcus is able to build up against the chemical enemies which seek its destruction. The profession has long recognized the fact that the malarial parasite becomes immune to the effects of quinine, and I am certain that the physician must eventually accredit the same phenomenon to the gonococcus. Personally, I feel that all pyogenic organisms possess the same characteristic and that, in the course of time, the treatment of all pathology induced by them, which calls for the local application of germicides, will be based on a general recognition of this theory.

Reasoning upon the supposition that the gonococcus may become immune or resistant to the bactericidal effect of a chemical which is being resorted to continuously and at short intervals to kill it, it is comparatively easy to account for that type of infection which responds to treatment at first, but which, later on, fails to do so. Here we find a clear instance of an acquired immunity to the drug

But what of the infections which do not evidence an initial response to the same chemical which produced results from the very beginning of the treatment of the other infections? Are these instances of special strain resistance, or of a natural immunity, or are they the result of an acquired immunity which was developed in the infecting host before transmission took place? It might be possible that certain of the twelve or more different strains of the gonococcus possess a resistant idiosyncrasy to an individual chemical, but this is a wide hypothesis to substantiate when we reflect upon the seeming ease with which the organism appears to take on or throw off this fastness in any or all infections. Without question, an infection may not be amenable to mercurochrome in the beginning but may later on react beautifully to that preparation. There is no logical reason to assume that an individual strain resistance would change in this manner.

However, it is highly probable that all of the different strains of the gonococcus, in time, will build up a slowly developed, somewhat persistent and general degree of tolerance to a germicide which is being employed very widely. As an example, the Valentine irrigation method, with dilute solutions of potassium permanganate, does not seem to be as universally effective as it was reputed to be when first introduced. But such tolerance appears to be the result of widespread chemical association or environment, rather than an inherent strain quality. It is relative and not absolute immunity. An infection may not respond rapidly to the Valentine system; but persistence in the treatment will eventually have

a debilitating influence upon the causative pathogerm and force it to capitulate in the end. In an absolute or natural immunity there never would be a response to treatment.

If we concede to the gonococcus the attribute of acquiring a germicidal immunity in one instance, we may with equal propriety grant it in other instances. It does not matter where, at what time, or in what manner this tolerance is acquired. If it can be acquired in one patient, it can be developed in another patient. Therefore, it requires neither a greater stretch of the imagination nor a more perfect digestion of actual facts to comprehend that a resistance may exist at the time an infection is transmitted from one individual to another as well as that it may develop in a given individual during the treatment of an infection which did not seem to possess it at first. The theory is either right *in toto* or else it is wholly wrong and untenable.

In the light shed by prolonged observation of the results of treatment of these infections, the solution of the enigma would seem to be that, since with the passage of time the organism builds up or loses a tolerance to germicides, the immunity is unquestionably acquired; that it is the result of chemical association or environment, and that it is but temporary. It seems to divide itself into two fairly distinct types: a sluggish type and a sudden type.

The sluggish type is slow in developing and is not characterized by an open and wanton disregard of bactericidal authority but by a sullen, rebellious indifference to it. For an instance, let us again refer to the Valentine irrigation method. For the past fifteen years this form of treatment has been more universally employed, perhaps, than any other. During this time, it seems that its potency has been slowly declining until now its effect in early Neisserian urethritis is often slow and gradual. Quite different from the result reported by Valentine wherein he secured a cure in fourteen days in the majority of cases (5). It is true that now and then we are able to get a brilliant result like this with our own cases today but this is not the rule. It is probable that, in those cases wherein we do obtain a showy result, the organisms causing the infection have not been recently subjected to potassium permanganate solutions and, for this reason, have acquired no resistance to that chemical.

We may refer to Keyes for an example of the sudden type (6). He remarks that an infection may react very readily to protargol for eight or ten days and then flare up into sharp acuteness. The infection is then flagrantly and violently in rebellion against protargol. If, however, the treatment is discontinued for a few days, the protargol solution may again adequately control the disease. This is undoubtedly an instance of quick, sudden but fugacious tolerance.

What effect does the recognition of this theory of germicidal adaptability, on the part of the gonococcus, have on the treatment of the disease? In the first place, it adds a thousand fold to the force of the modern urological teaching that each case must be regarded as an individual problem. The management of gonorrheal cases, *en masse*, according to a fixed and undeviating therapeutic system or standard would seem to be a questionable procedure, since it might prove to be an obvious and criminal waste of precious time to treat some infections in a manner which might be vastly inferior to some other method. It entails a more versatile attack against the gonococcus; compels a more thorough understanding of the action of the chemicals being employed and necessitates a sharp, rigid and consistent observation of their effect upon the disease.

At one time it was thought best not to attempt to check quickly the copious discharge from an acute gonorrheal urethra by the local application of chemicals, because their effect would tend to encourage a heightening of the inflammatory reaction and aggravate the existing urethral distress. If the local use of germicides did do this, then the attitude of the profession was right. I suspect, however, that the solutions then in vogue were too greatly concentrated or else lacked the present pharmaceutical range and refinement, because it has been found that germicides judiciously employed, in proper solution strength, will have the reverse effect, in that they will not only check the filthy, annoying discharge, but will allay the acute symptoms in a truly remarkable manner and shorten the course of the disease. The present trend of acute antigonorrheal therapy goes even further than this. If the effect of the germicide or germicides is not immediate or pronounced, the treatment is failing in purpose and recourse to a chemical which will induce a more ready response is in order.

The objective of modern antigonorrheal therapy is to localize the infection to the most restricted area possible and to kill it without undue loss of time. It is poor therapeutic policy to permit an infection to penetrate into the deeper urethral structures or to spread to its adnexal contiguities, if it can be avoided. It is equally poor policy to injure or devitalize the urethra, to its pathological undoing, by the injudicious use of strong chemicals. The sequelæ of ill advised urethral medication may be far worse, for the patient, than the disease itself. We should fully appreciate the fact that, while there are many obvious scientific reasons why we should seek to eradicate a gonorrhea quickly, there are also certain limitations to treatment beyond which we should never go. These limits seem to be the too frequent use of any germicide—all of which are more or less irritating—the injection of devitalizing preparations or the employment of solution strengths greater than the urethra will safely bear.

Any germicide which would uniformly prevent infection spread and rapidly kill the gonococcus without injuring or devitalizing the urethral tissue could be defined as an ideal gonococcicide. The alert practitioner recognizes the limitations of his therapeutic armamentarium in that, as yet, there is no ideal gonococcicide; but there are a number of preparations at his disposal which have a very decided lethal influence upon the gonococcus and, if he profits by a careful observation of the effects of local treatment with these, he will be enabled to select from the list one or more which will prove so antagonistic to the gonococcus that the average results will be quite gratifying.

The important point to remember is that all infec-

tions do not respond alike to a given gonococcicide in the beginning, nor is the action of any one uniform, invariable or consistent throughout the course of the disease, even though the infection may have been severely disciplined by it at first. Basing the treatment regimen upon these facts, the average length of time it requires to subdue a gonorrhea is materially lowered and, it is safe to say, the danger of complications and sequelæ is lessened.

What rules shall govern our conduct in the selection of a gonococcicide? This is a difficult question to answer because experience counts more heavily here than the assimilation of an abstract dissertation. I am tempted to approach the subject by dividing all cases into two classes: those which have received treatment before admission and those which have not.

In the former class, a careful case history will elicit information concerning the method and extent of treatment already undergone, together with the type of germicides used. Knowing this, it is advisable, since previous treatment did not produce results, to shift to some germicide not already called upon. Suppose, for example, the infection has been treated for some weeks with argyrol solutions. In this time, it has probably become rather extensive, while at the same time the causative organisms have become toughened by exposure to the silver derivative. If the infection is in an acute, frank stage, it is useless to consider argyrol further. The dye germicides or permanganate irrigations will serve a better purpose. If, however, the infection shows that argyrol has been having an inhibiting influence upon the inflammation and that it is in the declining stage, it is not advisable to discontinue argyrol altogether. Supplementary medication with some of the dye germicides or permanganate solutions will then bolster up and augment the effect of the argyrol. Alternation between a silver derivative and mercurochrome may not be good. Observation of the case will quickly determine this and then, if the results are not favorable, alternation with acriflavine, metaphen or mercurophen may be effective. In this class, the posterior urethra is almost invariably involved.

The situation presents a different aspect in the latter class. These infections, for the most part, are confined to the anterior urethra. The object of treatment is to select a method which will do two things: first, that which offers a minimum of mechanical assistance to the spread of the disease and, second, that which proves most antagonistic to the gonococcus in the majority of cases.

Under the first consideration, irrigations would seem to be contraindicated since there appears to be a greater percentage of posterior urethritis associated with this form of treatment than if gentle injection of small amounts of fluid is made into the anterior urethra with some type of hand syringe. This restriction rules out the most efficacious way of using potassium permanganate. If, however, the infection has traveled into the posterior urethra, there is no contraindication to irrigations.

It seems that the dye germicides, as a whole, will control an acute discharge more quickly and uniformly than any other class of gonococcicides. They have one great drawback. Their action is rather fugacious and, if they are employed at the frequent intervals necessary to control the disease, they often prove quite irritating; seem to cause an induration of the urethra and, by their pronounced diffusible and penetrative faculty, they seem to impregnate the urethral wall with the dye to such an extent that it is temporarily devitalized. These limitations should be constantly carried in mind or these powerful dye germicides may be quite harshly and unfairly condemned, when the fault really lies with the method of application. I find mercurochrome extremely valuable; but I do not rely upon it alone for two reasons: first, when used often enough to be curative in itself it taxes the urethra too much in the manner mentioned above and; second, the gonococcus becomes resistant to it, in many instances, before it will produce a cure. For these reasons, I alternate it with one of the silver derivatives. Should the urethra evidence either a deleterious or an irresponsive reaction to mercurochrome, alternation of the silver derivative with acriflavine or permanganate irrigations generally suffices to control the infection nicely.

While these dyes are unquestionably valuable in the treatment of gonorrhea, their effect must be carefully observed and they should be promptly discontinued if the urethra shows signs of chemical distress. They should be alternated with some other compatible gonococcicide so that it is not necessary to inject them so frequently. A urethra may tolerate a one per cent. solution of mercurochrome once a day very well for several weeks, while two or three injections daily may set up a severe reaction. Alternate gonorrheal therapy has an added value in that the gonococcus does not become resistant to two or more germicides as quickly as it will to a single one for the simple reason that it is not being subjected to the influence of any one of them as frequently.

In the strenuous and commendable search for gonococcicides which more nearly approximate the ideal, we must not lose sight of the fact that there are other factors, than the local application of germicides, to be considered in the treatment of gonorrhea. The regrettable tendency on the part of the gonococcus to migrate into the urethral adnexa is responsible for a more or less constant percentage of prostatitis and seminal vesiculitis. No solution, however diffusible and penetrating, will carry through to the vesicles. It is foolish to expect the impossible from a drug, and we should not look for a cure of the urethritis when an active contributing focus of infection exists within the adnexa, which is untouched by the medication. We may hold the urethritis in abeyance until the focus is eradicated, but we cannot cure it until that is done. Failure to detect complications may incline us to condemn unjustly the remedial properties of gonococcicides in many instances.

It has been the experience in this office that the procedure adopted by the German medical staff during the Great War, when followed here, has been responsible for a decided reduction in infection time in those cases in which the adnexa have been involved. The Germans instituted routine massage of the prostate gland and seminal vesicles during the second week of a posterior urethritis (7). By so doing, they found that sequelæ were more cer-

tainly insured against, complications minimized and infections shortened.

It is an obvious essential to rational treatment to eliminate contributing foci within the urethral adnexa. But here is a very important point to remember. An infected seminal vesicle may undoubtedly reinfect the urethra. On the other hand, a recrudescence of the infection within the posterior urethra may reinfect the seminal vesicle. For this reason we should not simply mark time with the urethral treatment while the prostatic or vesicular inflammation is subsiding. We should rather direct our efforts toward a coincidental and synchronous cure of each. Therefore, we see that the close observation of the effect of germicides within the urethra should never grow lax. A more constant and purposeful watch upon our gonorrheal cases will certainly prove worth while. Like safety upon the sea, which is obtained only at the price of eternal vigilance, the secret of success in the treatment of gonorrhea rests upon the same principle.

Sodium Salicylate Injections in Epidemic Encephalitis.—Courcoux and Meignant (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris,* May 8, 1924) report a case confirming the favorable results previously recorded in epidemic encephalitis by Carnot and Blamoutier, Rathery and Gournay from intravenous injections of sodium salicylate. In the authors' case, after nine days of ordinary treatment, without improvement, four grams of sodium salicylate in a four per cent. solution were injected intravenously on each of six successive days. Improvement was manifest by the second day, the somnolence disappearing, the patient sitting up in bed, the myoclonic movements practically ceasing, the urine output slightly increasing, the temperature gradually subsiding to normal, and the appetite later returning. Intravenous administration then becoming impossible on account of the small size of the patient's veins, treatment was irregular, partly by the mouth and partly by the intramuscular route and subarachnoid space for a few days, during which the symptoms grew worse again. Beginning eight days after cessation of the intravenous treatment, four grams of four per cent. sodium salicylate were injected daily into the muscles of the thigh for twelve days, then on alternate days. Improvement was soon apparent and continued progressively, the patient later requesting to be allowed to get up and eat. This improvement was slower than that which had followed the intravenous treatment. Nevertheless, the time relationship of the improvement and treatment seemed to show that the salicylate was active even when given intramuscularly, and this route therefore seems advisable where, for any reason, the intravenous route, which is the best, is unavailable.

Pressure Treatment of Varicose Ulcer.—G. Nobl (*Wiener klinische Wochenschrift,* June 26, 1924) asserts that the bacterial contamination of the varicose ulcer has no bearing on the course and the healing of the ulcer. The only etiological treatment is the relief of the stasis and congestion by pressure bandages, of which the dressings with rubber sponges and zinc gelatin are the best. In addition it is advisable to produce an artificial thrombosis of the veins with five per cent. carbolic acid and ten per cent. sodium carbonate solutions.

Treatment of Hemorrhoids by Submucous Injections of Chemicals.—H. Graeme Anderson (*British Medical Journal,* July 19, 1924) experimented with various chemicals, such as carbolic acid, quinine and urea, iron perchloride, ergot, lead acetate, alcohol, and formalin. He maintains that carbolic acid is the best of all, though quinine and urea give almost as good results. For the past few years he has confined himself to the use of carbolic acid and he believes that ten per cent. carbolic acid in equal parts of glycerin and distilled water is the best solution to use. With this solution, injected at the proper site, the best and safest results are obtained, and no complications such as pain, hemorrhage, sloughing, ulceration, and abscess formation should occur.

Intraarticular Injections of Sodium Iodide, a New Method of Treating Late Syphilitic Joint Affections.—Hermann Schlesinger (*Wiener klinische Wochenschrift,* June 26, 1924) says he has had good results with the intraarticular injections of between 0.2 c.c. and 1.0 c.c. of a ten per cent. solution of sodium iodide in the late joint conditions after other treatment has proved futile. This treatment is associated with little pain and the improvement is seen soon, sometimes even after one hour.

Local Anesthesia in Cystoscopy.—L. D. Keyser (*Virginia Medical Monthly,* October, 1924), after emptying the bladder completely of residual urine with a soft rubber catheter, introduces one ounce of a freshly prepared ten per cent. solution of novocaine into the bladder through the catheter. As the latter is being withdrawn, a further amount of the same solution is injected along the posterior and anterior urethra; for this purpose about one-fourth ounce of the solution is required. A small pledget of cotton impregnated with ten per cent. cocaine solution is then placed in the fossa navicularis to anesthetize the meatal region. Thus the mucous membranes of the trigone, sphincter and entire urethra are definitely exposed to a strong anesthetic solution. Ten to fifteen minutes are allowed to elapse before introduction of the cystoscope. In a series of twenty-five cases the anesthesia was almost perfect in all but two, in one of which the solution had been merely injected through the anterior urethra, probably not reaching the trigone or sphincter—the points subject to most irritation in cystoscopy. No spasm of the ureteral meatuses was encountered in the series.

The Natural History of Hyperthyroidism and Its Significance

JOHN ROGERS, M.D.
New York

A simple hypertrophy of the thyroid is the most common kind of goitre. If this is accompanied by the symptoms of fatigue, that is, by mental and physical asthenia, with pallor and evidences of gastrointestinal inactivity, and thyroid feeding then affords relief, the condition is called one of hypothyroidism. The extremes of muscular fatigue, by the way, are accompanied by a fine or coarse tremor or socalled nervousness, and this is just as common in hypothyroidism as in hyperthyroidism.

INFLUENCE OF ENVIRONMENT

The exact cause of the hypothyroidism and the mechanism by which it is brought about are unknown. But, in adults at least, the most prominent symptoms, or those of fatigue, point first towards the environment. Worry, hard work and too little sleep are such commonplace attendants upon everyday life, and so often followed by other neuroses, especially of the gastrointestinal tract, that their relationship to the biochemistry of the thyroid is difficult to prove. It is only possible to surmise the cause and its effect by the sequence of events. An adverse environment requires a greater expenditure of energy than one which is favorable for the individual under consideration. After a simple hypertrophy, or goitre, becomes perceptible, it always increases in size and vascularity when the environment is adverse. When it is favorable the goitre shrinks. Exactly the same changes usually take place during the course of acute or chronic infections or immediately after traumatism. All of these circumstances require in the bodily resistance more or less expenditure of energy, and as it increases so does the goitre and its vascularity. That is, the goitre, after it appears, evidently enlarges in direct proportion to the activity of the bodily metabolism, which means energy expenditure, and hence, because of the known relationship of the thyroid to metabolism and to the general process of oxidation, it is reasonable to believe that the function of the thyroid is, through its secretion, to promote the production of cellular energy.

A socalled nervous person is only one who reacts to environment with more than the usual energy. Why men of this type are commonly afflicted with pylorospasm or gastric ulcer, while the corresponding kind of women often suffer from goitre is unknown. But, clinically, this seems to be the rule. Because the goitre, after it becomes perceptible, evidently enlarges under conditions which require energy expenditure and shrinks when they are eliminated, it is presumable that the simple hypertrophy begins as an automatic attempt at compensation. The gland enlarges in response to some mechanism which calls for more secretion than can be supplied by the thyroid of normal size. If the ingested iodine is insufficient to make the requisite amount of secretion, there should be the same response, and this has been made reasonably certain in animals by the observations of the agricultural department. But feeding iodine to man is believed to prevent only a moderate proportion of the cases, and after the development of the simple hypertrophy it cures still fewer. That is, there are other factors in the pathological physiology to be considered. As yet, we can only surmise these in the environment and in the acute and chronic infections and in traumatisms, which all seem to be related to the thyroid through its promotion of the production of cellular energy.

The most common response in the thyroid to an assumed overstrain of this character is the simple hypertrophy of the gland, and the next most common of this organ's abnormalities is the condition known as that of hypothyroidism. It is given this name chiefly because of the relief of the subjective symptoms which follows thyroid feeding. If this feeding is pushed to an extreme, it is easily possible to change the preexisting quiet to a rapid pulse, and that, or tachycardia, is the most characteristic evidence of the condition called hyperthyroidism. To make the diagnosis, only the obtuse require the aid of the calorimeter.

PULSE CHANGE

The change from the normal to the fast pulse rate can be induced rapidly or slowly, and is in direct proportion to the amount of the thyroid feeding. The same change can sometimes be brought about in hypothyroidism by the administration of excessive amounts of iodine. More often, however, iodine in hypothyroidism is entirely inert. It seems only to be capable of inducing the disturbance in those cases in which it brings about a preliminary swelling or enlargement of the gland.

It is a matter of common observation to note that the continuation or intensification of an adverse environment in states of exhaustion or pronounced fatigue will speedily produce a tachycardia. When the environment is not strenuous or when rest is obtained the tachycardia disappears. It only becomes pathological or characteristic of hyperthyroidism when the tachycardia persists and there is present a goitre. The same events take place in the presence of an increasing infection or traumatism, or of a psychological disturbance, although the latter is synonymous with an adverse environment. In other words, a hypothyroidism which is recognizable as a fatigue condition with the coexistence of a goitre, can be often observed to change into the less common hyperthyroidism. The rapidity of the change is in proportion to the stress or the presumable demand for the production of energy. Usually it takes place more or less slowly, and the tachycardia is at first apparent only after exertion or excitement. This is sometimes called the mixed hypothyroid and hyperthyroid disorder. With rest and with relief from the infection or traumatism, but always with rest, the hypothyroid state is predominant. With intensification of the strain the tachycardia and the goitre with its vascularity become more prominent, and there may finally be added the striking symptom of exophthalmos. How that is brought about no one knows, but experience proves that it means a much graver prognosis than the simple hyperthyroidism.

ETIOLOGY

Clinically, therefore, it is reasonable to believe that hyperthyroidism is merely a terminal manifestation of a primary failure in the function of the thyroid. It apparently begins with a simple hypertrophy of the gland in an automatic attempt to promote the production of cellular energy. If the organ is inefficient, either because it cannot obtain enough iodine or because it is unable to metabolize an abundance of that element, the resultant condition is the same, or that of hypothyroidism.

This condition of apparent functional failure, in its early or milder stages, is not demonstrable by the calorimeter but only by subjective symptoms. It should occur in the presence of a goitre, which is required to promote the production of more energy than it can sustain, but the resultant symptoms of fatigue can seldom be relieved by the administration of inorganic iodine.

THYROID FEEDING

All of the symptoms, with the exception of the goitre, are quite amenable, however, to the right kind of thyroid feeding, especially if this treatment is combined with rest, which means with relief from the need of energy expenditure. If this relief is not provided, that is if the energy expenditure is continued or intensified even though thyroid feeding is continued, there is sure to follow a more or less constant tachycardia. As remarked before, without altering any other factor, the same change can be induced by excessive thyroid feeding or more rarely by the administration of excessive amounts of inorganic iodine.

There is apparently some indeterminable stage of hypothyroidism, or presumable inefficiency in the thyroid epithelium, when its biochemistry alters, at least in man. Before this stage is reached thyroid feeding relieves, while afterwards it intensifies the symptoms. Tachycardia, as remarked before, is the regular reaction of exertion or excitement upon any ordinary extreme of fatigue, and is characteristic of hyperthyroidism only by its persistence. Ordinarily, the tachycardia in the beginning is not persistent or constant but intermittent. It represents, as in everyday weariness, an irritable rather than a rapid heart rate, but sooner or later if the need for energy expenditure is not relieved, the pulse becomes regularly rapid and this, in conjunction with a goitre, constitute the unmistakable signs of the final stages of what appears to be a failure of the thyroid. There is no doubt that the disease may develop with apparent suddenness, but this suddenness is probably only apparent.

The most common, or regular, course seems to be that outlined above, and should therefore be treated at least with circumspection. These patients seem to have a weak point in the important and complicated chemical mechanism which supports all the bodily activities. Their thyroids do not all have the normal and rather remarkable powers of regeneration which are shown in a few other organs, and the indiscriminate sacrifice of the gland shows enough bad results to make the surgeon cautious. The development of the socalled toxic adenoma, or localized tumor, in an otherwise normal gland which is accompanied or followed by tachycardia, seems to be only an incident in the process outlined above. It may be connected with congestion and a punctuate hemorrhage with irritation of the immediately surrounding tissues.

But however it may originate, the tumor presumably interferes by pressure with the normal functioning of the adjoining cells, and when these fail to fulfill the automatic demands upon them, the hyperthyroid condition may sooner or later supervene. But the "toxic" adenoma is just as frequently accompanied by hypo as by hyper signs, and either condition can be relieved by its excision. The nomenclature should not be allowed to confuse the outline of the story which begins with a simple hypertrophy of the thyroid apparently to compensate for the promotion of more energy production than the gland of normal size can supply. The next stage is that of failure, or hypothyroidism, and the next that of the irritable pulse of extreme fatigue rather than the regularly rapid pulse, and the next that of constant tachycardia or hyperthyroidism. The gland may be overactive, but it apparently represents not an excess of normal vigor, but a failure.

TREATMENT

The best treatment is, of course, the recognition of the natural history of the disease and its prevention in the early stages. Few realize that there are any differences in the medicaments commonly used for thyroid feeding. When administered for hypothyroidism some are much more toxic or much more likely to be followed by tachycardia than others. Probably the least toxic is the thyroid nucleoprotein material. A glycerin extract of the whole gland is somewhat more potent, and now can be obtained in five minim or ten minim pills. The ordinary tablets made by dessication of the entire organ are less reliable.

Etiology and Pathogenesis of Tertiary Syphilis of the Thyroid Gland

PIERRE GUILLAUME, M.D.
Bordeaux, France

The thyroid gland is not frequently the seat of tertiary syphilitic lesions and few cases have been reported. As to why this gland should be relatively free from luetic processes may perhaps be best explained by Mendel's theory, viz., that the colloid substance secreted by the vesicles contains a certain amount of organic iodine whose antiseptic properties are unquestionable. Now, this iodine is constantly being thrown into the circulation, irritating the thyroid, and it would appear that this is a sufficient reason for preventing the treponema from becoming lodged anywhere along this vascular network. It is difficult to conceive how a gumma, which melts away under the action of iodine, could develop in an organ which is the principal reservoir of organisms of this metalloid.

Nevertheless, gummatous or sclerogummatous tertiary thyroiditis occurs. What are its causative factors? In the first place, the process can only develop in an organism already infected, either congenitally or by acquired infection. Therefore the personal and hereditary antecedents of the patient must be carefully gone into when there is any suspician of syphilis and the modern tests for detecting it carried out.

Now, in an old syphilitic subject, what may be the conditions under which a gummatous or sclerogummatous process develops. Let me say at once that in congenital syphilis we are dealing with a true septicemia from the start. Just as in acute miliary tuberculosis, the gummata are generalized; they are to be found throughout the organism, not merely in the thyroid, but in the liver, suprarenals, lungs, thymus, and other organs. In acquired syphilis a preexisting goitre was for a long time thought to be an important predisposing factor, and Kocher said, "Just as goitrous thyroids are a prey to general infectious processes, which preferably produce a thyroiditis, so syphilis is more prone to develop in preexisting goitre, which decreases the resistance of the thyroid gland." This opinion, sustained by Mendel, Bérard, and Zoeller, seems to me rational, and in twenty-six cases collected by me there is only a single instance of preexisting goitre; therefore it may be supposed that syphilitic strumitis is exceptional.

Tertiary thyroiditis is somewhat more frequent in women and to back up this classic opinion (Bérard) it has been pointed out that the gland has many periods of perturbation, namely, during puberty, menstruation, pregnancy, and the menopause. Of the twenty-six cases referred to, five were in infants whose sex was not stated, eight in men, and thirteen in females. Hence, tertiary syphilis of the thyroid is slightly more frequent in women.

As to the age at which the process develops, it would seem that the youngest subject was a girl of eighteen years (Professor Guyot's case), with congenital syphilis. Of twelve cases of acquired syphilis in which the patient's age is mentioned, the average is forty years, but Küttner has recorded the case of a patient twenty-seven years old, while in the museum of the Royal College of Surgeons, there is a specimen taken from a female sixty years of age. Seven out of the twelve patients varied between thirty-eight and forty years of age.

The influence of cold, trauma, or profession, seems to be quite unimportant, while I find no instance in which a former thyroid infection—specific or otherwise—played any part. Nevertheless it is probable that a secondary syphilitic thyroiditis—which so frequently occurs without being noticed—may have placed the gland in a state of miopragia which by impairing its secretory function, will later on hinder its defensive action against syphilitic infection. We know then little definitely of the intimate causes that induce the treponema to attack the thyroid in the tertiary period, and as Fournier said, "Tertiarism attacks an organ as if by chance, the causes of this localization being unknown." The thyroid gland does not escape this rule.

I shall now make an attempt to explain, not the why and wherefore, but the how of the process by which the treponema becomes localized in the thyroid in the tertiary phase of the infection. This attack appears to take place in three distinct ways, the first being by the circulation, a classical theory. The spirocheta carried in the circulation penetrates the vascular network of the thyroid and comes into contact with the thyroid vesicles. Usually the iodine compounds contained in the gland make it impossible for this organism to remain in it, but if on account of former morbid changes the iodine is not fixed by the gland, the infectious agent will be in a condition to attack the walls of the vessels producing lesions of the adventitia, the intima, or even the three coats of the vessel. A secondary cell infiltration is the consequence of this vascular inflammatory process and will assume the form of a perivascular sleeve. The treponema may also break through the vessel walls, penetrating the connective tissue and thyroid parenchyma. Hübschmann has been able to detect the organism within the cells. The specific organism continues to provoke—during its various peregrinations—an abundant embryonal cell infiltration which gradually will dissociate the glandular elements, giving rise to circumscribed nodules.

According to the evolution of the cell infiltration towards fibrous organization or to necrobiosis, one will be dealing with either sclerous lesions or gummatous processes. If the two are combined they finally end in the sclerogummatous form. However, I would add that the higher histological elements of the gland are relatively respected and the syphilitic changes are more prone to involve connective tissue and bloodvessels.

Such is the classical theory. It does not exclusively explain the gummatous or sclerogummatous lesions of the thyroid, and in my opinion it can only explain the occurrence of lesions due to congenital syphilis, either early or late, as well as certain circumscribed gummatous forms of acquired lues. But in the sclerogummatous and ligniform types, the thy-

roid seems to be attacked by way of contiguity. Quite recently Dr. G. Monod has shown that Riedel's disease or chronic ligniform thyroiditis, usually has a syphilitic basis and is accompanied by important lesions of the trachea which, according to him, are even the starting point of the thyroid process.

According to Dr. J. B. Davies, a tracheal or laryngeal syphiloma may easily provoke an inflammatory reaction in the neighboring tissues which, as Lecène points out, produces a true more or less diffuse cervical cellulitis which gradually surrounds the thyroid, compressing it, and from this compression changes are set up.

It likewise would seem as if this same process is frequently the causal factor of syphilitic sclerogummatous thyroiditis. In ten of my collected cases of this type of lesion, the notes of two are incomplete so that they need not be considered; in a third case autopsy did not reveal any involvement of the trachea, but in the remaining seven, tracheal lesions were present in all, such as crude or ulcerated gummata or cicatricial stenosis, revealed by laryngoscopy or autopsy; and in my judgment these findings are quite sufficient for adopting Lecène's opinion. But if this opinion is accepted, it means that the thyroid is secondarily involved by contiguity or compression. Briefly put, the conclusion infers that all cases of tertiary ligniform or sclerogummatous thyroiditis are uncommon yet possible complications of tracheal syphilis. This problem requires further study. In the two most recently reported cases, those due to Poncet and Lerich and Monod, the histological interpretation is in favor of this hypothesis, the gummatous necrosis being in these cases, as Alamartine points out, inflammatory and not vascular in origin.

Lastly, there remains a third, although quite hypothetical, manner of action of the syphilitic virus, namely, the possible action of the toxins of the spirocheta on the thyroid in the tertiary period. In point of fact, these toxins have so far received little attention from laboratory workers. But there is no valid reason that they do not exist. If the toxin of tuberculosis—which does exist in fact—is capable of producing the inflammatory tuberculoses of Poucet, why should not the toxin secreted by Schaudinn's organism be capable of producing similar effects?

By analogy, let me recall the researches of Roger and Garnier, who demonstrated some years since that injections of attenuated cultures of the tubercle bacillus produced a progressively developing sclerosis which ended by transforming the thyroid gland into a fibrous mass containing only some islands of normal thyroid parenchyma. To my way of thinking, the toxic action should be admitted. Therefore, syphilitic toxins may produce an inflammatory reaction of the connective tissue (sclerosis) of the thyroid gland, with complete atrophy of the gland cells sometimes ending in myxedema, as shown by Pospelow, in 1894.

This observer reported a case of myxedema complicated with diabetes insipidus, which was cured by antisyphilitic treatment, and he believes that a syphilitic sclerosis of the thyroid was the cause of the process. The patient had presented characteristic primary and secondary accidents and, when the myxedema developed, there was a gumma of the testicle. The thyroid was hard and slightly increased in size.

Adenoma of the Thyroid*

RALPH R. MOOLTEN, M. D.
New York

In a previous paper we have given the clinical classification of affections of the thyroid gland, employed in this clinic.

The only condition in which there is a physiological gland is adolescent goitre. In all the other conditions, there is a pathological gland, with varying degrees of increased or diminished secretory activity, or with dysfunction.

There is probably no disease that has brought about as much theorizing and speculation as to etiology on the one hand, and biochemical and physiological changes on the other, as diseases of the thyroid gland. Eliminating theory and speculation, there remain three outstanding facts concerning all conditions of the thyroid gland. These are: 1, Anatomical changes in the gland. This produces a change in size. 2, Functional changes of the gland. This is responsible for the clinical symptomatology. 3. The end results of these two forces. The active agent has ceased to operate, but the irreparable influence on the heart, the liver and the kidneys is left behind.

Goitre of adenoma may be associated with hyperthyroidism; or it may occur without any evidence of thyrotoxicosis. Whatever the clinical symptomotology may be, there is no strict differentiation between the histological pictures. Hypertrophy and hyperplasia cannot be distinguished. Between them there is only a difference of degree of progress of the same exciting cause. The character of the end results remains the same, regardless of what may be the influence that primarily induces the thyroid enlargement.

Changes that constitute simple hypertrophy may be designated, seriatim, as: enlargement of the thyroid; increase in vascularity; a softening in consistency of the gland; a diminution of the iodine and colloid contents; an increase in the size of the acini, with variability in size and outline; and, an increase in the size of the epithelial cells. Should there be a continuance of the exciting mechanism that prompted the hypertrophy, these changes increase in degree, and, in addition, there is added actual

*From the Surgical Service of Professor Charles Gordon Heyd, New York Postgraduate Hospital. Read before the Surgical Conference, New York Postgraduate Hospital, April 10, 1924.

proliferation of the epithelium of the acini; the formation of new acini; and infoldings, in the form of papillary projections, into the lumen of the acini. These changes constitute hyperplasia. Allan Graham states: "It is almost inconceivable that the thyroid can jump from its normal state into a well-marked hyperplasia, without there having been some degree of simple hypertrophy, unless the hyperplasia is a manifestation of malignant new growth."

Marine classifies adenomatous thyroids into two types: Type A.—Diffuse colloid adenomatous goitre; Type B.—Fetal adenoma, subdivided into, 1, pure fetal, 2, intermediate, 3, colloid. These subdivisions refer to the degrees of differentiation of cellular arrangement, ranging from undifferentiated embryonal tissue to the highly specialized arrangement of the normal, fully developed gland.

Two theories present themselves to explain the origin and nature of Type A (i.e., diffuse colloid adenomatous goitre). Probably each contributes its share. The first is that this type is a progressive change of a true fetal adenoma, in which the individual adenomatous buds had been of a very highly differentiated and specialized order. The second suggestion is that diffuse colloid adenomatous goitres originate in old, long standing colloid goitres, in which large amounts of the colloid material had been absorbed. This absorption may be occasioned by the injudicious administration of iodine and thyroid products, or by an increased activity, essentially in the gland. The result is the phenomenon of hyperplasia, notably an increase in the number of acini, and in infolding and projecting of the epithelial cells lining the ascini. In any event, this type possesses certain definite characteristics. It is always present in both lateral lobes; the individual nodules are made up of acini that are rich in colloid, and do not make tumors of any considerable size; the capsule is thin; this goitre practically never undergoes malignant degeneration; the individual masses are never lobulated. Histologically, diffuse colloid adenomatous goitre bears a close resemblance to the normal gland.

The palpatory diagnosis is of a diffuse, soft, symmetrical enlargement of the thyroid. The thrill is not so markedly present as it is in Graves's disease, nor is the auscultatory bruit. If toxic changes take place, there is likely to develop an asymmetrical enlargement of the active lobe; or single or multiple discrete nodules. However, the toxic symptoms may develop without this change in anatomical contour, which makes it resemble type B.

Type B (fetal adenoma) is more definitely a tumor than type A. This type of goitre has its origin in socalled Wölfler's rests, which are remnants of embryonal tissue left over from the developmental period of the thyroid. These embryonal remnants, laid down in intrauterine life, may be present in one or both lobes, either singularly or in number. The size of the nodules so formed is variable, and the histological appearance depends on the developmental stage of the individual nodule. Hence, in the same gland there may be clumps of opaque, grayish, undifferentiated, embryonal tissue, having no colloid material and no acinar arrangement of the epithelial cells; together with fully developed fetal adenomata, in which there is much colloid and iodine and in which the acinar arrangement resembles the normal thyroid gland. The degree of differentiation is responsible for the subdivision of fetal adenoma into pure fetal, intermediate and colloid groups.

The palpatory diagnosis depends upon the gradation of the process. There may be an enlargement of an entire lobe of the thyroid, or merely a firm discreet mass, in a lobe. Again, there may be multiple, smaller nodules, disseminated throughout the entire gland, giving the thyroid a pebbly feel. It lacks the homogeneous enlargement of Graves's disease.

Although adenoma of the thyroid may occur at any age, it most frequently makes its appearance in the early twenties. The potentiality for the development of the fetal adenoma is congenital, for the Wölfler's rests are laid down during intrauterine life. Once having made its appearance, the course of thyroid adenoma varies. Whereas in some there is an apparent arrest of the process, the only evidence of its existence being its actual presence, in others it will enlarge, producing pressure symptoms, or take on toxic changes. Malignancy of the thyroid almost never occurs except in those glands in which there had been some prior adenomatous pathology.

In those cases where toxic changes have set in, there is usually a history of a period of about ten years during which there had been a palpable enlargement of the thyroid gland, unassociated with any other symptoms. The onset of the evidences of toxicity is insidious, in contradistinction to the comparatively acute summation of symptoms in Graves's disease. The patient usually states that at a certain time she began to feel nervous, and to have attacks of accelerated heart action. But usually about three years elapse before the palpitation, the nervousness, the tremor and the other evidences of thyrotoxicosis have sufficiently developed to oblige her to seek medical aid.

Barring the injudicious administration of iodine and thyroid products to those patients who already have an adenoma one is at a loss to explain the mechanism that prompts the change from a nontoxic to a toxic adenoma. There are four periods in the course of existence that stand out as the occasions when most goitres are developed or make their appearance. These are, 1, intrauterine life; 2, puberty; 3, after repeated pregnancies; 4, the climacteric. As a fifth period that has no definite chronological occurrence, we may add any situation that would tend to exert an unusual and excessive strain on the endocrine and sympathetic nervous systems. In consequence, we are usually able to synchronize the development of toxicity with the occurrence of a severe mental or physical shock, be it summated at once, or the summation of a succession of oft repeated minor insults, as, for example, the accumulated intoxication from a long standing focal infection. Failing in this, we are constrained to attribute the thyrotoxic change to an iodiopathic or essential aberration of functional activity.

Patients with goitre of adenoma, seeking medical attention, naturally fall into one of three clinical groups. The first is composed of those who are

concerned because of the cosmetic effect of a swelling in the neck or who fear the later consequences of such a swelling. The second group comprises those cases who suffer pressure symptoms from the swelling. The third group comes because they are troubled with the symptoms of thyrotoxicosis.

The main point of clinical differentiation between the thyrotoxicosis of adenoma and of Graves's disease is that the former lacks the eye signs that are characteristic of the latter. The tumor, the tremor, the tachycardia, the nervousness and the emotional unstability are present. In general, the cardiac symptoms are most prominent. In Graves's disease, the selective action of the intoxication is for the nervous system; in toxic adenoma it is for the cardiovasular system. There are cases which have been treated for paroxysmal tachycardia before the presence of a toxic adenoma had been discovered, and to which the cardiac condition was not attributed. With treatment of the goitre, the cardiac manifestations disappeared. The point of difference is that in paroxysmal tachycardia, the paroxysm disappears as suddenly as it comes on; in toxic adenoma, the drop is more gradual.

The basal metabolic rate is not as high in toxic adenoma as it is in Graves's disease. The actual figures, however, must be considered in a relative sense, and not, per se, taken as an indication of the toxicity. A case of toxic adenoma with a basal metabolic rate of plus 50 may be less toxic than a case of Graves's disease with a reading of plus 30.

TREATMENT

Treatment, if instituted at all, is always surgical. If the adenoma is quiescent, it may be left alone. However, frequent examinations, and at least biannual basal metabolic determinations must be made, to determine the presence of toxic change. This expectant manner of handling a case is the preferable one until the patient is well past adolescence. (3) This allows time for a firm equilibrium of the endocrine system to become established. Under no conditions must iodine or thyroid products be administered over any protracted period, for this will cause a nontoxic adenoma to become toxic. The effect of small, controlled doses of iodine on the basal metabolic rate may be used as a diagnostic test.

If at any time pressure symptoms, or any evidence of toxicity, intervenes, surgery is indicated. If surgery is not employed in the nontoxic cases, one must always bear in mind the potentiality of a nontoxic goitre of adenoma to become toxic, or, more remotely, malignant.

The Absence of Endemic Goitre in Honolulu

J. CHRISTOPHER O'DAY, M.D., F.A.C.S.
Honolulu, Hawaii

The goitre problem of the Pacific Coast, particularly of its Northwest portion, is still unsolved. Toward such a solution there has been no little endeavor, yet up to the present time no reward has been claimed. As a result of my own investigation the conclusion was reached that endemic or retentive goitre had to do with the character of the drinking water. This conclusion, however, was based entirely on personal and the general observation of others. The problem in no way is able to lend itself to actual scientific research, and this in the face of the fact of our work being carried on in a district where endemic goitre enjoys an incidence of close on to fifty per cent., namely, Portland, Oregon.

With the cooperation and guidance of no less able clinicians than Lawrence W. Selling and Franklin C. Maclean, interest in the etiology of retentive goitre gave way to that of those hypersecretive types that were accompanied by a diabetic syndrome. When further work and observation showed that this diabetic syndrome would entirely clear after lobectomy we set about to discover, if possible, just what it was in these odd cases of Graves's disease that was directly responsible for the loss of the carbohydrate tolerance.

First, was there a lesion of the sympathetic system which caused the hypersecretion of the thyroid? If so, was the same lesion capable of disturbing the secretion of the islands of Langerhans and thereby precipitating the diabetic syndrome? Again, could the hyperthyroidism produce the extreme thirst, polyuria and the ravenous appetite and the glycosuria be but a mere metabolite? But when it was continuously and invariably observed that the metabolic rate was always in proportion to the degree of hyperthyroidism and that the basal metabolism was in no way related to the carbohydrate overthrow our questions were forced to go unanswered.

In a subsequent article Selling emphasized the point by showing that the degree of hyperthyroidism bore no relation whatever to the precipitation of the diabetic syndrome.

It was during this time that Maclean was carrying on the research work, the result of which has been published (1).

The sugar content of the blood in diabetes of thyroid origin is as variant as that of the pancreatic lesion and resolves itself into that last conjecture of a hypothetical sugar threshold. But the hyperglycemia and increase of the metabolic rate which are constant findings with hyperthyroidism cannot be regarded as a step toward the development of the

occasional cases wherein the sugar mobility assumes the rôle of the pancreatic lesion.

While this reference to hyperthyroid goitre is foreign to that which the title of this article more reasonably suggests it is mentioned since it is now known that Lugol's solution is quite capable of re-

FIG. 1.—Japanese patient with hyperthyroid goitre.

storing both the carbohydrate tolerance and a marked return toward the normal metabolic rate. But the improvement is not permanent and a second administration of the drug is disappointing.

Up to a certain point only is the iodine able to stay the storm,—at that point help is needed. Whatever that help may be remains to be discovered. That the kidney function might be the factor, has nothing beyond the notion to sustain it. The results of our observation and investigations have been published (2).

Endemic or retentive goitre has not been observed in Honolulu. It was this fact which led to our comparing the water supply of the island city with that of the goitre districts of the Coast. Before making such comparison it may be of interest to mention, in brief, the presence of toxic goitre among the Oriental races of the islands.

It should be recalled that the percentage of toxic or hyperthyroid goitre is no greater within the endemic districts than it is, generally speaking, throughout the United States and Canada. This type of goitre is encountered in Honolulu but just what incidence to population has not been learned. While it is among the Japanese that it seems to be the most prevalent, once comparison is drawn between the Japanese population, the predominant of the Orientals, it immediately is made to appear that toxic goitre here occurs in about the same proportion as that noted throughout the mainland and Canada.

In this reckoning the native Hawaiian cannot be included for the type of individual that is prone to this affliction is but too seldom met among this phlegmatic people. It was Dr. Wayne Babcock of Philadelphia who first drew my attention to this, the consideration of types.

The first change necessary to start the development of endemic or retentive goitre is that which takes place in the character of the thyroid's secretion. Its consistency becomes viscid to a degree wherein it is no longer able to enter the stomatae of the lymph radicles. Accumulation within the follicles results and the gland is made to bulge proportionate to the degree of accumulation.

We conjectured that some definite arrangement existed between the secreting follicles and lymph radicles and which, if understood, would eliminate the speculative conclusions of which there were two namely,—was the thickening of the thyroids' secretion due to a faulty functioning of the follicles or was it the result of a scanty lymph supply into the follicles for the physiological thinning of their secretion? In other words, just how did the mineral free water exert its deleterious influence on the interdependence of thyroid and lymph commingling?

With this in mind a number of normal thyroids were injected, several methods of injecting being used, but no one of the subsequent sections threw the least light on the mechanics of the interrelated function of blood supply to that of lymph and the gland's secretion.

With a preponderance of evidence to support the belief that endemic goitre is caused by the character of the drinking water it is interesting, at least, to find further proof of comparing the character of the drinking water of Honolulu with that of the districts where this disease is prevalent.

The artesian water with which the city of Honolulu is supplied is one of the finest drinking waters in the world. It is unique in its low content of sodium iodide and which seems to be bound in a rather unstable way with an equally low content of the chloride of soda and potash. Calcium carbonate represents the highest per cent. of mineral content yet insufficient to cause the water to be hard. Its bacterial count is nil.

FIG. 2.—American patient with hyperthyroid goitre.

The artesian wells providing this water vary in depth from five hundred to nearly one thousand feet. An average of twenty feet deducted from the depths of each well will place the remaining number of feet below sea level.

The discrepancy in the depths of the wells is due to the elevations and depressions in the roof of the artesian basin and not to the surface location of the well. The almost continuous rainfall of the moun-

tain tops has to percolate through thousands of feet of volcanic ash, lava rock and in many places substrata of ectopic coral before reaching the artesian basin. From this it may be readily understood how such altitudes would place the plus pressure on the side of the artesian basin and prevent the waters of the ocean from finding their way into the basin.

A Plea for Discontinuing the Use of Pituitrin in Intrapartum Practice*

D. DEUTSCHMAN, M.D.
New York

The tendency in the modern practice of obstetrics is towards the recognition of the fact that parturition is not a normal process but a pathological condition and the act of delivering the child is a surgical procedure and should, therefore, be accorded the same careful considerations that are observed in all other surgical cases.

With the advancement of modern conception of biological science, this fundamental branch of medicine, obstetrics, is being gradually taken out of the hands of the oldfashioned midwives and other quacks and placed on a scientific basis, the same as all the other branches of medicine and surgery.

To achieve the results of shortening the course of labor, numerous therapeutic agents have been introduced into the field of obstetrical practice, the most popular one is pituitrin, an extract derived from the posterior lobe of the pituitary gland. This drug is unreliable in its action, frequently resulting in prolonged and complicated maternal and fetal morbidity and increased mortality. But it is, nevertheless, used extensively and indiscriminately by a large number of general practitioners.

The profound physiological effect the pituitary extract exerts upon the uterus during the parturient stage, in increasing the tonus of the uterine musculature, has stimulated the obstetricians to adopt and use it as an oxytocic agent and place it as the vanguard of the obstetrical armamentarium.

Citing a short history of this uncertain drug, which is so extensively abused by a great number of physicians in their practice of obstetrics, will not be out of place and is as follows:

In the year 1909, Blair Bell read a paper before the Liverpool Medical Institute, reporting his experimental work with pituitrin in the treatment of placenta previa and Cæsarean section. Following these reports of the English biochemist, the laboratory men in Germany continued experimenting with this drug in obstetrics and loudly proclaimed the wonderful work and results achieved by this therapeutic agent in the practice of obstetrics.

The fame of this drug crossed the Atlantic, and according to tradition, everything emanating from Germany, so pituitrin gained rapid recognition on this continent and the medical profession in this country, having the stamp of approval of the German medical authorities, began to consider pituitrin as the magic drug which was going to substitute all our mechanical and therapeutic aids in the practice of obstetrics and was going to solve the perpetual problem of difficult labor cases, shorten the course of labor and, naturally, reduce labor pains ad minimum.

The first reports from Germany, stating that pituitrin was devoid of all dangers, made our American colleagues feel that obstetrical forceps and all the other mechanical and therapeutic aids in complicated labor cases were relegated to the past. The logical deductions one could draw from those reports were that all a physician needed was a hypodermic syringe and needle with a few ampules of pituitrin and he would be ready and fully equipped to cope with any complication that he might be confronted with in his practice of abnormal obstetrics.

While the medical men in this country were hailing the introduction of pituitrin in the field of obstetrics as a wonderful achievement, suddenly, like a bolt from a clear sky, Professor Edgar, of the Cornell Medical School, disillusioned them by reporting his experience with this drug in his hospital and private obstetrical practice. In an article (1) this famous obstetrician warned the medical profession not to be overenthusiastic over this drug. He stated:

"We consider the use of pituitrin in obstetrics as a dangerous practice, liable to cause death or deep asphyxia of the fetus, premature separation of the placenta, uncalled for deep cervical lacerations and possible uterine rupture."

Following this first warning to the medical men, similar reports began to appear in the medical literature reported by obstetrical authorities in this country and abroad. In looking over the literature on the subject of pituitrin as an aid in obstetrical practice one is surprisingly impressed with the change of opinions of the leading obstetricians regarding the usefulness of this drug in intrapartum practice.

It is the unanimous opinion of the leading obstetricians that this drug has no minimal, safe or effective dose; some patients do not respond to it at all even after the injection of several ampules and others have a precipitate labor immediately after the administration of a few minims of it.

Pituitary extract when administered even in the smallest dose during the process of parturition, frequently throws the uterus into a state of violent tetanic contractions the period of which may last from fifteen to thirty minutes. This condition of uterine contractions is beyond the control of the doctor in charge of the case, interfering with the uteroplacental circulation sufficiently to cause the death of the fetus. This same condition of the tetanic contractions may result in rupture of the uterus, especially if dystocia is present.

Owing to the uncertain and dangerous action of this drug, many physicians have modified the use of

*Read before the Bronx County Medical Society, October, 1924.

pituitrin by giving it when the head is on the perineum. But even under this circumstance, the same violent contractions may cause extensive lacerations of the maternal soft parts and may cause intracranial hemorrhages of the newborn.

When the condition of tetanic contractions follow the administration of pituitrin it cannot be remedied any more, unless the patient is immediately put under deep anesthesia and a rapid forceps extraction performed. Most of our leading obstetricians have given up this pernicious drug as an aid in the obstetrical activity, even in their hospital work where conditions are more or less ideal for emergency requirements which may result from the use of pituitrin.

Of all the deleterious drugs, in my humble judgment, pituitrin stands out preeminently as the one drug which markedly increases maternal and fetal mortality and morbidity of mother and child. Hirst of Philadelphia in a recent article on the use of pituitrin gives this drug a prominent place as an etiological factor of fetal and maternal mortality.

De Lee of Chicago said the following about pituitrin: "I consider pituitrin as a criminal agent if administered before the delivery of the child. All this drug does, is provide for the physician and his brother gynecologist a lot of chronic sufferers, often incurable even after mutilating operations. I am aware of twenty ruptured uteri due to pituitrin."

This statement was made by the eminent obstetrician at the convention of the American Obstetricians and Gynecologists and none of the delegates present at that scientific session attempted to defend the usefulness of this drug in intrapartum practice.

Winn, in a recent article on pituitrin as a dangerous drug when used as an obstetrical adjuvant, intimates that the only excuse for its employment is ignorance. He states: "If there is an indication for interference with forceps and you know how to use them, why don't you use them in preference to this dangerous drug?"

The advocates of pituitrin in intrapartum work assert that the dangerous effects resulting from this drug are due to any one of the three following causes: 1, improper dose; 2, improper indication, and 3, improper surroundings.

That these assertions are at variance with true facts may be shown by statistics collected and compiled by medical authorities of their own school, on the effects of this glandular extract. Mandel, himself an advocate of pituitrin in the practice of obstetrics, made an exhaustive study of the effects of this extract upon the mother and child, by analyzing a series of 1,293 cases and the results (2), as published under the title The Present Status of Pituitary Extract, are as follows:

Ruptured uteri	12 (1 in 106)
Fetal mortality	34 (1 in 38)
Asphyxia pallida	41 (1 in 32)

Ingraham and Chase give the following dangerous results of this popular drug, which is so extensively used by a number of general practitioners and which, at one time, was reputed as being devoid of all dangers:

Number of cases treated	33
Number born asphyxiated	6
Fetal deaths	2
Severe postpartum hemorrhage	7

A few figures taken from the records of the Virginia Memorial Hospital, which has a large obstetrical service, will not be out of place. Two series of equal number of cases treated impartially, with and without pituitrin and the following are the results:

No. cases		Infants' deaths
With pituitrin—34		8.8 per cent.
Without pituitrin—34		3.4 per cent.
Free from laceration	First degree laceration	Second degree laceration
32.3 per cent.	35.3 per cent.	32.3 per cent.
68.4 per cent.	27.1 per cent.	11.8 per cent.

I would like to emphasize that these figures were obtained under ideal hospital surroundings and managed by highly competent, impartial, actively engaged obstetricians.

Some physicians have discarded this drug in obstetrical practice, but not entirely, using it only in cases of socalled uterine inertia and in the third stage of labor. But does this condition, called uterine inertia, justify the risk of administering this pernicious drug, which may prove fatal to mother and child, especially when used by the general practitioner in patients' homes without the proper conditions for emergency requirement?

Professor Edgar, in an article on pituitrin, states: "Pituitrin should never be employed for uterine inertia in any stage of labor, unless anesthesia is at hand and preparations have been made for immediate operative delivery should the accident of uterine rupture follow its administration."

But what is that condition called uterine inertia, which would in any way justify the injection of an uncertain, dangerous drug? This is, as we all know, a condition of muscular atony or relaxation of the body of the uterus resulting from uterine overexertion following usually a tardy and prolonged course of labor. It is a state of physiological reaction following a prolonged and continuous hyperstimulation of the uterine musculature, caused by the secretion of the pituitary gland upon the susceptible uterus during the various stages of labor.

This condition of uterine inertia is, therefore, one of uterine exhaustion. Like any other muscular organ the uterus loses its strength, power of contractility and tonicity after it has undergone a prolonged process of muscular contractions. It finally acquires a state of muscular exhaustion during which condition the uterine muscles do not respond any more to the stimulating effect of the pituitary secretion, which is normally present and supplied by the pituitary gland through the various stages of labor. Uterine inertia is a normal physiological reaction, nature intends the uterus to rest, in order to regain the normal strength of its muscles. Practically and rationally we should, in this condition of uterine relaxation, administer an anodyne, instead of the pituitary stimulant, to help the work of the physiological process.

To my mind it is a physiological error and a rationally therapeutic contraindication to continue artificially stimulating an already overstimulated organ, when the latter is in the course of returning to its normal or preexhaustive state of muscular tonicity and contractility. This biological axiom holds true for all animal organs, be it the heart, the stomach, the intestines or the brain. Then why should the uterus be an exception to this physiological law?

With regard to the usefulness of pituitrin during the third stage of labor mentioned previously, I wish to make a short quotation from an extensive report by Reist and Gugenheim (1).

1. The average duration of the third stage was not shortened. Occasionally it was prolonged by the appearance of a stricture at the internal os of the cervix, the formation of Bendal's ring.

2. The average loss of blood was not diminished and the antihemorrhagic effect was not observed. The profuse hemorrhages were increased.

3. Disturbances during the third stage occurred more frequently, because the placental labor pains induced by the pituitrin often appeared before the uterus reached the stage of retraction.

As we see, there is no benefit derived from the use of pituitrin even in the third stage, on the contrary, complications frequently result. With regard to the effect this drug has upon the newborn, may be seen from an overwhelming number of fetal deaths reported in the medical literature, even by the strongest advocates of pituitrin as an obstetrical aid. The causes of these fatal accidents are numerous; the most common of which are the following:

1. The violent and prolonged uterine contractions with the very short intervals, caused by the administration of this drug may result in the constriction of the placental cite, thereby limiting or cutting off the blood supply to the placenta, causing the improper oxygenation of the fetal blood which inevitably results in asphyxia neonatorum.

2. Premature separation of the placenta.

3. The constriction of the cord between the uterine wall and some fetal hard part, such as sacrum, trochanter or shoulder, produced during a violent and prolonged uterine contraction. In addition to the dangerous effects upon the fetus and the maternal pelvic organs, pituitrin also exerts a deleterious strain upon the heart muscle.

1. By raising the blood pressure it throws an additional load upon the heart.

2. By causing the constriction of the coronary vessels it lessens the flow of blood to the cardiac musculature and thus interferes with the proper nutrition of the heart itself.

While I am opposed to the use of pituitrin in the practice of obstetrics, I do not want to be accused of defending the policy of *noli me tangere*. I believe it is the duty of the physician to lessen the pain of childbirth and shorten the course of the process.

In conclusion I wish to state that the results as reported by the leading obstetricians in the literature point definitely to the undeniable fact that pituitrin, in the field of therapeutic usefulness in the practice of obstetrics is limited. It is a drug too dangerous and too unreliable even in the few cases where it may be indicated. This drug carries with it more dangers than benefits to the patient.

I wish to close with the following remarks by Dr. Haskell: "We do not wish to convey the impression that the use of pituitrin always results in catastrophe; the vast number of cases in which there was no apparent injury renders this attitude absurd. We do believe, however, that there is always the possibility of harm resulting even from the socalled safe dose a danger so real that it is scarcely justifiable to risk it for the sake of the few added hours of rest or those left free to be devoted to other tasks by the obstetrician."

The author's references will appear in his reprints.

Some Problems Which Endocrinology Presents

IRVING PARDEE, M.D.

New York

The problems which endocrinology presents today are presided over by two groups, one composed of physiologists and research workers, and the other the clinicians. The former stands superior within the confines of his laboratory and experimenting on isolated tissue and nonhuman animals announces his results to a receptive world. The latter busily caring for patients and numerous hospital duties approaches the human being and pragmatically cures patients and draws conclusions which are often astounding and are said by the research worker to be unscientific. This is the age long fight between the two, but together, and in the hands of both, really lies the ultimate future of our fullest knowledge of the glands of internal secretion. Up to the present time the odds are entirely in favor of the clinician for most of the syndromes described, and the therapeutic advances have come from their efforts.

The main difficulties which seem to rise in our path are, first, to which gland or combination of glands belong a particular series of symptoms, and second, what are the fundamental factors which produce these glandular dyscrasias; and lastly, wherein do we fail in a therapeutic approach?

The symptoms which patients present that are superficially explained or called "nervous" are often unsatisfactory both to the physician and the patient. Many of these we are beginning to classify and will undoubtedly in the future elaborate in the classical syndromes of diseases of the glands of internal secretion. Take, for example, the young girl who becomes suddenly fat, has headaches, and grows hair on her chin, arms and abdomen; or one whose menses stop suddenly at twenty-two with the development of headaches and five years later shows the early signs of acromegaly, optic atrophy, etc. If these symptoms, which later show themselves to be unquestionably due to the pituitary, had been recognized at their onset, how much more chance they would have for a future of health without growth deformity.

Into what group are cases of socalled migraine going to fall. At the present time many of them are materially helped by glandular medication and surely

their clinical picture of low blood pressure, slow pulse, low blood sugar and CO_2 combined with vomiting of a reflex type, bordering on the acidosis picture, suggests an obscure biochemical glandular basis. How many headaches are pituitary in origin? The typical pituitary headache which (1) I described in 1917, located intratemporally, is now commonly accepted but there are many which have not such a striking location.

What proportion of the subjects who are chronically below par, presenting fatigue syndromes, varied stomach and intestinal symptoms, showing idiopathic skin diseases; women who have days and weeks of physical discomfort and economic interference because of menstrual difficulties, for which no definite organic foundation can be determined; unless we invade the realm of the endocrine glands.

My first interest in this subject began at the Neurological Institute, where it was found that there was a large group of patients whose symptoms were not due to organic neuraxial diseases, they were not due to a mental disease, nor to any psychological maladjustment expressed as a hysteria or a psychoneurosis. A definite approach was found possible along the lines of endocrinology, it explained their symptoms, it provided a therapeutic approach. The endocrine field in nervous diseases is ever widening with our advancing knowledge of the interpretation of the glands of internal secretion and nervous symptoms. Other pioneers in this field are not primarily neurologists and because of their broad interests are developing possibilities in another group of patients. Draper (2) of New York, by accumulating anthropometric data, has attempted to classify certain definite types subject to gallbladder disease, renal disturbance, etc., while Englebach has approached the endocrine glands from the broad viewpoint of the internist.

We are familiar with acromegaly, myxedema and hyperthyroidism and their symptoms are well accepted, but the factors which lead up to the production of the syndromes are facts which most of us feel incompetent to state. Cases of acromegaly may be due to numerous causes and it is rare to see only the pituitary gland involved. This is true of practically all endocrinous disorders; there is a delicate balance between the glands, some being antagonists, some synergists.

The popular vogue of one of our present day postcard publicity drug firms is due to its leader having capitalized this knowledge, and working upon the old "shotgun" fallacy, has formulated a series of pluriglandular mixtures prescribed by number in order to make it easy for the physician and save him the trouble of learning. It is my belief that to prescribe any gland without a definite indication known to oneself is not only unscientific but bad practice.

Under these circumstances symptoms must be correlated with a particular gland and though it is known that several glands seem to produce the same symptoms, it is our province to so analyze them as to eventually localize it to a single basic gland. With the further elaboration of glandular syndromes, this will become more and more possible thus eventually solving the first of our difficulties.

In trying to bring this about we must not overlook any of the diagnostic aids. It is necessary to observe the conformation of the bones externally, which include facies and skeletal disproportions and abnormalities; the progress of ossification at the epiphyses; the size, shape of the sella turcica and its comparison with the patient; the presence of a thymic shadow in the upper mediastum; whether there is a tubular heart as in status thymic lymphaticus, etc. Radiography will reveal all these. The texture of the skin, its color, its tendency to moisture or dryness, its reaction to stroking with the finger, its growth of hair, both as to quality and distribution, and its tendency to production of fat and deposition of pigment, are also important diagnostic aids. Likewise must be considered the shape and development of the teeth and nails. The muscular status is at times disturbed and indicates a possible endocrinopathic basis. The genital development is subject to considerable variation in glandular disorders and must be correlated with the remainder of the picture. Keen clinical observation is necessary to observe slight variation from a supposed norm and who of us really has the normal bodily conformation? Are we not all therefore the product of our glandular balance or imbalance? Blood pressure under basal conditions, pulse variations, oculocardiac reflex and the reaction of these to certain drug injections, such as adrenalin and pilocarpine, should be noted.

Beyond this it has been found that in the laboratory field many tests are of great value, but a heightened basal metabolic rate does not always mean a hyperthyroidism, nor does an increased blood sugar a pancreatic diabetes. A sugar tolerance curve serves as a differentiating aid, while a low blood sugar, as our experience with insulin is teaching us, will give symptoms almost as trying as though too high. The blood carbon dioxide, calcium, and coagulation time may show variation in certain endocrinoses, as may the blood count. Many biochemical disorders of the blood are as yet quite beyond our diagnostic acumen but within this field is a large opportunity to expand our knowledge of endocrinology.

If we wish to state briefly the accepted clinical judgment as to tissue growth in relation to a particular gland we must look upon bony growth as being dependent upon the thymus, pituitary, thyroid and gonads. Skin conformation, i. e., texture, color, etc., upon the thyroid and thymus; hair type upon the thyroid, pituitary, adrenal (cortex), and gonads; teeth upon thymus, pituitary, thyroid, adrenal (cortex), gonads; genital development upon thymus, pituitary, pineal, gonads, and adrenal (cortex); muscular growth and function upon pineal; parathyroids, perhaps also the adrenal. In addition to these tissue alterations or variations dependent upon the endocrine organs the blood pressure has controlling it the pituitary, adrenals, and thyroid blood clotting gonads, adrenal, thyroid; sugar metabolism pancreas, pituitary, adrenal and thyroid, etc. This list, though not complete, gives a definite idea as to the interdependence of function and the unquestionable polyglandular nature of all endocrine dyscrasias. The possibility of one gland being alone disturbed is seemingly improbable, the combinations being as many as the variants. One gland, however, is basically diseased while the others become so in an effort

to compensate or because of a failure in their interdependence.

The second large difficulty which besets our progress is largely from a deficiency in our knowledge as to etiology.

Inherited determinants in the field of glandular organs are subjected to the same laws as govern other biological structures. Mendel's (3) original hypotheses apply likewise to the endocrine glands, but dominants and recessives in their reactions produce widely different results upon individuals and one family may produce a great variety of glandular syndromes. Endocrinopathic inheritance determines our physical type throughout and we therefore show resemblances to our parents, or just as often to a more distant relative. Goitre families are well known, families of giants are common, as are dwarfs, and how common it is that a marked variation in height occurs between a husband and wife; the result being a *more perfect* endocrinological offspring.

A study of family anthropological types will reveal often interesting data and glandular dyscrasias will be found; dwarfs, diabetes, giants, goitre, etc., all in the same family group. What then the inheritable factor? It may be a stock deficiency running through the entire family, e. g., pituitary, thyroid, etc., the clinical syndromes occurring as a reaction of that particular individual to the family deficiency. This is seen very commonly and emphasizes the acute importance of family charts in caring for these patients.

The occurrence of certain epochal milestones in our life history with their resulting glandular rearrangements makes for a possible error in their development. At birth the existence of a congenital absence of the thyroid, gonads, etc., is evident when the maternal circulation no longer supplies the necessary hormones. This is really more due to a developmental defect perhaps contributed to by an endocrinopathic inheritance. The next outstanding epoch which both sexes must meet is that which occurs in the passage from adolescence to maturity, namely puberty. A striking readjustment of glandular balance occurs at this time, the thymus gland has gradually atrophied, the pineal is beginning to be calcified, both of the organs ceasing to function normally by this period. This cessation of function seems to be connected with the proper and normal development at puberty of the gonadal elements, perversion of function resulting in accelerated or retarded sexual growth or failure of proper sex differentiation. With the normal appearance of the secondary sex characteristics, including hair growth, change in voice, development of the mammæ, etc., accompanying puberty, is the accretion of growth and the final set of the bony and bodily build as determined by the pituitary, thyroid, gonads, etc. An extraordinary emotional and intellectual change occurs also at this time, probably the stability of our emotional life at this period depending upon a proper balancing of our endocrine sympathetic chain. In the female the pregnancy epoch is another time when glandular disturbance may occur and we frequently see thyroid dyscrasias, a thickening of bones and tissue with headaches due to pituitary disorders, obesity and numerous other signs obviously glandular. The final epoch is the menopause, when with a cessation of ovarian activity there is commonly associated momentary hyperthyroid episodes and more rarely a goitre or myxedema. The normal symptoms of the menopause are due to an ovarian thyroid imbalance, while abnormal symptoms often involve many of the endocrine organs. Let us not forget there is also a definite male menopause which, though it has its glandular components, is strikingly a period of psychological readjustment and it must be reckoned with clinically from time to time. Thyroid, orchitic and rarely corpus luteum (in those of *feminine* type) may be of avail in these cases.

Another interesting basic causative factor in the production of endocrinopathies is trauma. Owing to the location of the pituitary gland at the base of the skull, it is in a favorable site for injury. That this occurs is borne out by facts because syndromes referable to disturbances of its function have been repeatedly seen as a sequel of head injury. Fractures of the base with direct involvement of the sella turcica or hemorrhage about it are the most common cause; while fractures elsewhere with resulting contra coup are seen; while trauma of the skull even without fracture has caused pituitary injury. Our more recent knowledge through excellent experimental (4) work opens up a wide field of speculation because of the association of hypophyseal syndromes with a lesion of the hypothalamus and floor of the third ventricle, so therefore it seems possible that basilar injuries may disturb either structure and produce signs of glandular dysfunction. Acromegaly, Froehlich's dystrophiagenitalis, diabetes insipidus, etc., are seen as the result of these traumata. Injury rarely causes any functional disorders of the thyroid parathyroid group, while because of the deep seated position of the adrenals they rarely show symptoms. However, deep abdominal injuries and high lumbar traumata may cause signs of sudden adrenal depletion with shock followed by a chronic hypoadrenalemia. Injury to the testicles rarely produce any dyscrasia but ovarian trauma from pelvic operations or very rarely from without may cause acute or chronic hypoovarian symptoms.

Another exogenous factor producing an endocrinopathy is infection. In childhood the contagious diseases are frequently a starting point for the long history of a chronically unhealthy child, very often due to thyroid and adrenal disease produced by their toxins. This is particularly due to the toxins of scarlet fever, diphtheria and poliomyelitis, while the orchitic and ovarian atrophy resulting from mumps is well known.

In adolescence, influenza and its closely related cerebrospinal disorder, epidemic encephalitis, are the cause of many endocrinous symptoms. Hypopituitarism, hyperthyroidism, hypoadrenalism, etc., are types commonly seen after these diseases. Certain other cerebrospinal infections and diseases affect the pituitary, pineal, etc. Certain chronic diseases also have a predilection for the endocrine glands. Tuberculosis chiefly involves the adrenals, causing low blood pressure, pigmentation or a true Addison's disease, while its concomitant thyroid picture often makes an early differential diagnosis impossible from hyperthyroidism. Pottenger's first interest in the sympathetic nervous system and the glands of inter-

nal secretion seemed to come through observations among his tuberculosis patients. Syphilis will cause pituitary syndromes, tabes dyspituitarica being a symptom complex described before anything much was known about either of these conditions. A hypothyroidism is seen accompanying lues, as is sometimes an adrenal disease.

Chemical deficiencies, either exogenous or endogenous, are important factors in maintaining a normal function of the glands of internal secretion. Those in the northern part of New York State must fully realize the importance of iodine. Rochester and numerous middle western cities have added it to their water supply. Others are considering doing the same in those parts of the Great Lakes district which fall within the iodine deficient or goitre belt. This district also includes certain parts of northern New England and large areas in Europe, around the Alps, in the Carpathians, and in southeastern Russia. A knowledge therefore of the individual's geographical history becomes essential in understanding an endocrine disorder. A proper chemical concentration of iodine is essential for the full utilization of thyroid, though its other metabolic components are not now appreciated. Sodium iodide or Lugol's solution must be used not only from the viewpoint of prophylaxis but also in the treatment of colloid goitre, hypothyroidal states and in those cases which suggest iodine deficiency. We have found a definite group of cases with hyperthyroidal symptoms even simulating the Graves's syndrome which have been cured by iodine and thyroid extract.

The problem now before us is this; if iodine assumes such an important rôle in the stabilization of our bodily economy, particularly the thyroid, what other chemical elements must we reckon with in order thoroughly to understand our endocrine etiology. Calcium is an important adjunct to parathyroid function, while the ingestion of too much sugar will result in an endocrinopathic defect. In this latter connection the rôle of the islands of Langerhans have been purposely omitted from this paper because they are so thoroughly considered elsewhere. Certain of the metabolic poisons, lead in particular, seem to have a predilection for the endocrine glands. In one family group a member of our clinic, the original glandular dyscrasia came from a grandparent who was a painter, muscular dystrophy being the final endocrine endproduct. Other chemical and biochemical products must undoubtedly play a large part in producing endocrinopathies if our knowledge were only capable of grasping them.

Tumors either of the gland itself or pressing upon it from without will produce either destructive or irritative symptoms. These may be of a teratomatous type, or benign, or malignant. The association of tumors of the suprarenal cortex with sexual peculiarities is quite well accepted at present, due no doubt to the known common embryological origin of that structure and the gonads. Other glands present clinical syndromes familiar to all of you, though we must not overlook the fact that a very destructive tumor of any of the glands mechanically speaking is quite possible without any distortion of tissue or growth occurring, e. g., complete destruction of the middle fossa may occur with involvement of the pituitary without any acromegalic or hypopituitary signs, though local neurologic signs may be prominent. Why this is possible is not yet understood.

Within the realm of our psychic life we acknowledge a close interrelation with endocrine glands. McDougal (5) says that our temperament is dependent upon a proper balancing of our bodily organs and of course of these the glandular mechanism is predominant. The temperament being a fundamental almost instinctive element of our personality, the larger conception is also true.

We therefore must look upon the personality as having an organic element in our endocrine glands which factor has presumed one overenthusiastic writer to fill a book on this subject. How much they condition our personality is not known but those who see patients in both fields are struck by the predictable personality characteristics on the basis of more easily diagnosed glandular type.

Emotional crises resulting in hyperthyroidism, adrenal disorders, and pituitary diseases are not infrequently seen, while who of you have not known of cases where menstruation ceased acutely or chronically on the basis of some emotional shock!

Conversely, we see endocrinopathies resulting in disorders not only of the personality, but invading the realm of psychopathology. Any psychiatric hospital will show its quota of hyperthyroids, cretins, myxedema, hypoovarian states especially at the menopause, and if we are to accept the more recent researches of Mott, dementia precox is etiologically a testicular disorder. A large group of the psychoneuroses have associated with the psychological maladjustment a glandular imbalance which is amenable to therapy.

There are undoubtedly many more etiological factors producing endocrinopathies, but here again we have only as yet scratched the surface of a fuller understanding of the causes.

Something is wrong with glandular therapy. This thing is the cause of our therapeutic failures and it lies basically in the realm of biochemistry. What a change has occurred in the treatment of diabetes since a new method of extraction of the pancreas produced insulin. Our diagnostic acumen has far outstripped our therapeutic results. For one reason we have had a smoke screen thrown upon us by the venders of pluriglandular formulæ, mixed glands, and hormotones. It will take some time to shake off their deleterious effect upon our therapeutic skill. In addition we are provided with single gland products in dried form, extracts, and in ampules for hypodermic use. The latter are better standardized and do not deteriorate, while the former two do not conform to these demands and neither are they particularly fresh. And yet you and I use them constantly, sometimes obtaining striking effects and again not. Then again for example, take adrenalin, it represents probably one of the many substances secreted by the suprarenal gland and this gland has two distinct portions. Some say it has no effect except by hypodermic injection; that may be so, as measured by laboratory methods, but why does it cure certain types of seasick individuals when given under the tongue or in the back of the throat? Pituitary, thyroid, corpus luteum, ovarian, parathyroid, all have an effect when given by mouth but failures are seen.

The millennium of glandular therapy will arrive when it has been possible to extract from each gland its many chemical components so that stimulative and substitutive therapy are possible. To do this is without the realm of our present knowledge and it is upon this field that we must concentrate in order to hasten the day. When it comes there will be an "insulin" or several "insulins" for each gland of internal secretion.

The author's references will appear in his reprints.

Observations in the Mildest and Earliest Cases of Diabetes Mellitus

A. GALAMBOS, M.D.
New York

As a rule both in clinics and in private practice the twenty-four hour urine is collected and used in making the dextrose test. The life insurance companies are becoming more cautious than formerly and demand samples of urine voided two hours after a test meal in doubtful cases.

In the mildest and earliest cases of diabetes mellitus the glycosuria is intermittent. The dextrose concentration of the blood on fasting is normal or at least below the renal threshold value. When carbohydrate rich food is taken, the blood sugar may reach, or temporarily exceed, the renal threshold for dextrose and may cause transitory glycosuria. The duration and the degree of the glycosuria depend in the individual case upon the severity of the disease and upon the form and quantity of the carbohydrates ingested. In the mildest cases the rise of glycemia may last only for an hour, or even for a few minutes, and the glycosuria which is usually very slight is also present for this short period only.

Transitory glycosuria is characteristic of Maclean's renal glycosuria and also for those cases of diabetes mellitus which were described by Maclean as showing "lag" curves, i. e., cases in which the glycemia after administration of glucose surpasses the renal threshold, but returns to normal within two hours. In both instances the blood sugar concentration returns to the fasting value within two hours and the glycosuria cannot last longer than that time, and is usually of shorter duration.

In true diabetes mellitus the time required for the rise of the blood sugar and the duration of the glycosuria are as a rule longer, but even in these cases the glycosuria is intermittent in character. It can also occur that a more prolonged hyperglycemia is followed by a shorter period of glycosuria, for example in cases in which the elevation of the blood sugar value remains for a shorter period above the renal threshold value and there is a relatively longer time during which the value lies between the highest normal and the renal threshold value. In all these cases it may easily occur that the twenty-four hours' urine is free from sugar and so no diabetes can be detected by the analysis of the *collected* urine. In the same cases, however, careful examination of the urine samples voided at short intervals after the ingestion of carbohydrate rich food, or after the sugar tolerance test, may still reveal dextrose. When several samples are taken during ten to fifteen minute intervals, it may happen that dextrose can be detected in only one or two of them, possibly in a very low concentration—merely traces or in amounts ranging from 0.10 to 0.15 per cent. Again it may be that the two hours' urine after the test meal contains some slight quantity of sugar, but when the bladder is emptied after four or five hours, the sugar reaction in this portion of the urine may prove negative. It also may occur that the two hours' urine does not give a positive dextrose reaction, but that one or two of the fractional portions, voided separately at fifteen minute intervals, does react positively.

The making of a decision as to the nature of a slight quantity and postcibal temporary appearance of dextrose in the urine, which is, according to the writer's recent observation, rather a frequent finding, is often very difficult. Sugar tolerance tests of the urine and blood must be resorted to in such cases and the results of this test may decide this important question. A positive test can be considered as proving the case. Failing increase in the degree of glycosuria in the fractional urine portions after administration of fifty or one hundred grams of dextrose, or lack of hyperglycemia, or return of the blood sugar to the fasting glycemia value within two hours, leaves the case undecided and requires further observation and renewed examination.

The result of the sugar test also depends to a great extent upon the concentration of the urine. Benedict and others (Newirth, Kast, Crole, Meyers) found that the normal urine collected in twenty-four hours contains about one gram dextrose, and also that 0.05 per cent. concentration of dextrose is the minimum amount which can be detected by the usual laboratory tests. When a normal person voids two litres of urine in twenty-four hours, the sugar test is negative, while when the urine is more concentrated and the daily quantity does not surpass 0.75 or 1 litre, the concentration of the dextrose in the urine may reach 0.10 per cent., which can readily be recognized by positive sugar test. When the same quantity of dextrose is diluted to two litres, the reaction may be negative.

In the mildest, earliest, or suspicious cases of diabetes mellitus the urine should be examined during the two hours following the ingestion of a carbohydrate rich diet or test meal. Special attention should be given to portions of the urine taken, at fifteen to thirty minute intervals during the period from forty-five to seventy-five minutes after administering the test meal. The dextrose test in the twenty-four hours' specimen is not adequate to decide the important question of a beginning diabetes.

This leaves the matter of the blood sugar estimation an open question. When before the test meal the blood sugar is normal and the sugar test in the urine is negative, but after the test meal the blood sugar rises above the physiological threshold, diabetes mellitus is present. If the blood sugar does

not exceed the normal renal threshold (0.18 per cent.), there is no diabetes mellitus. In this latter case, if glycosuria appears, Maclean's renal glycosuria may be postulated; if both the glycosuria and the hyperglycemia (above the renal threshold) are absent, no pathological condition whatsoever is present. If after the test meal the blood sugar returns within two hours to the value before the test meal was taken, there is in the absence of glycosuria no pathological condition present; or if glycosuria sets in, Maclean's renal glycosuria or diabetes mellitus with "lag." Marked delay in return of the blood sugar to normal, even in a case showing no glycosuria, is suggestive of diabetes mellitus.

The tolerance for carbohydrate in diabetes mellitus can only be insufficiently expressed and characterized by one number. Different amounts of carbohydrates can be tolerated according to the carbohydrate percentage of the foodstuffs. A diabetic may have a tolerance for one hundred grams, taken in foodstuffs containing fifty or over fifty per cent. carbohydrate, while the same patient at the same time can tolerate, without glycosuria, two hundred or even more grams of carbohydrates taken in vegetables containing three to five per cent. carbohydrates.

Aside from the quantity, the manner of the distribution of the carbohydrates ingested can modify the degree of the tolerance manifested by the patient —whether the same amount of food is taken at one time, or is divided into two, three, and four parts, naturally influences the utilization of the carbohydrates. In expressing the degree of the tolerance it is important to give the figure for twenty-four hours, but it is equally as important to *express the tolerance for the single meals.* When a diabetic can utilize seventy-five grams carbohydrate taken at one meal he can tolerate 150 grams of carbohydrate, when he takes one half of this amount twice a day, 225 grams when he takes one third the amount three times a day. It is important to divide the carbohydrates to be given in twenty-four hours into three nearly equal parts, or even a smaller fourth additional meal can be taken at a late evening hour, especially when the third meal, the supper, is taken at an early hour. I will not say that it is of no consequence from the point of view of the tolerance whether the system becomes charged or overloaded with the maximal dose of the carbohydrates that are well tolerated, once, twice or three times a day, even though the blood sugar elevation with the following glycosuria disappears within the period of time between two meals; on the other hand, the failure would be still greater if one did not take advantage of the ability of the system to metabolize the carbohydrates within a few hours and to be ready after that time to utilize the next similar carbohydrate ration.

It is also of great importance to know, and well worth while emphasizing the fact, that a diabetic usually can tolerate much more carbohydrate in the evening than in the early morning hours. Taking this into account, the proper division and distribution of the carbohydrates should always be arranged to the best advantage of the patient.

In the mildest cases of diabetes the proteins should only rarely be restricted, i. e., in cases in which administration of protein actually increases the degree of the glycosuria. As cases of this type are very seldom met with, one need not often resort to this measure.

The diet, in the mildest cases, should differ from that of a healthy man as little as is absolutely necessary. To impose a strict and unnatural diet in such cases is neither necessary nor wise.

Desiccated Gonadal Substances*

HERMAN SHARLIT, M.D.,
and JEROME SAMET, M.S., Ch.E.
New York

In an earlier communication one of us in collaboration with Corscaden and Lyle (1) presented a theoretical consideration of the problem of preparing for oral administration organic tissue wherein the chemical nature of the therapeutic principle or principles was unknown. Based on such considerations we prepared whole ovarian substance, began a clinical study of its value and felt justified in the conclusion that whole ovarian substance was a specific remedy for the socalled flash symptom of the menopause. Further clinical study (2) impressed us with the genuineness of the therapeutic value of the desiccated whole ovarian substance.

We must bear in mind the fact that all observers are not using identical chemical mixtures in ovarian feeding. In theory, at least, this offers a difficulty that makes it impossible for the present to accept a negative result of one observer as offsetting a positive one for another. Therapeutic failures may still be ascribed to improperly prepared gland substance.

Ignorant of the chemical properties of the units we are seeking to preserve in the preparation of gonadal tissues we must aim to retain in the finished product, as nearly as possible, all the physicochemical properties of the many entities in the untreated materials. More specifically this means: 1, avoiding the coagulation of the protein; 2, the liquefaction of the fats, 3, oxidation reactions, 4, reduction reactions and, 5, hydrolytic cleavage. Such results can only be attained by desiccation done rapidly at low heat and high negative pressure (in vacuum) in the presence of a minimum of circulating air (oxygen). Significant differences in the technic of preparation of gonadal substances ought to show themselves in the findings obtained from such simple procedures as the determination of ether soluble and water soluble fractions in samples of the finished product.

*The Plaut Fund for Research in Internal Medicine, Harriman Research Laboratory, The Roosevelt Hospital, New York City.

The products from three different sources were analyzed. Product A was prepared after the directions outlined in a previous publication. Products B and C were ordered in powder form direct from two of the better known manufacturers. We had the manufacturers of C furnish not only their stock powders of whole ovaries and corpora lutea, which are made primarily from the cow, but also similar materials wholly from the sow, from which latter animal the ovarian products A were prepared. A study of the table given below with special reference to the values of the several fractions in products C indicate that the animal source of the substance may be ignored as a factor in our findings.

Ether soluble fraction.—The analyses show that all the C products are defatted and that orchic product B is also defatted. Much speculation has been offered upon the proposition of the therapeutic utility of gonadal lipoids. While no definite conclusion is available the indication to the pharmaceutist is distinct. He should strive to preserve these fatlike bodies. Defatting should be proscribed. If the ether soluble fraction in the dried material is over twenty per cent. it is difficult to pulverize the material; for this fat mixture tends to adhere to the attrition prongs of the pulverizer and shortly succeeds in clogging the machine. This is the case with orchic substance and we imagine that it is for this reason that the manufacturers of products B resort to defatting for their orchic substance while avoiding it in their ovarian materials. Nevertheless, with extra effort and care in pulverization it is mechanically possible to reduce orchic substance to powder without defatting. Since it is impossible to know the extent of the changes induced in a highly complex organic mixture by the use of a fat solvent—or indeed by the use thereon of any chemical agent,—we must in the light of what we are endeavoring to accomplish by proper desiccation, consider a chemically treated mixture as a preparation distinctly inferior to one not so treated.

Total nitrogen.—These values call for no particular comment. These tissues contain about eleven per cent. nitrogen after desiccation. Where the material has been defatted there is of course a percentage increase in nitrogen measure. This accounts for higher nitrogen figures in defatted products.

Total soluble nitrogen.—These fractions were estimated from extractions with distilled water, a very faintly acid or neutral solution and water made slightly alkaline to phenolphthalein. Throughout all the samples there is greater solubility in alkaline solution. Extractions in alkaline medium tend to bring the nucleoproteins into solution and we may reasonably ascribe to this fact the greater solubility in the alkalinized water.

Given in the last two columns of the table is the percentage measure of the soluble nitrogen for both the neutral and alkaline water extracts. For the comparable extractions products A show from fifty per cent. to one hundred per cent. greater values for the soluble fractions of the total nitrogen. This is a sizable difference. It indicates a defect in the technic of preparation of products, B and C. It seems a fair assumption that these latter products have been submitted to too high a drying temperature; this resulting in the coagulation of some of the protein. As opposed to products A those of B and C may be considered as desiccated with high heat. It would lead us into needless and futile speculation to theorize on the many other possible by-effects upon complex organic materials in the presence of elevated temperature; increasing reaction rate, aiding oxidation and favoring hydrolysis and other factors.

PRODUCT	Ether soluble	Total nitrogen	Soluble nitrogen water (neutral)	Soluble nitrogen water (alkaline)	Nonprotein nitrogen in water (neutral)	Nonprotein nitrogen in water (alkaline)	Per cent Total N soluble water (neutral)	Per cent Total N soluble in water (alkaline)	Tissue
A.	16.0	11.1	4.8	6.1	2.6	1.2	43.0	55.2	Whole Ovary
B.	14.7	11.4	3.1	3.8	1.7	1.4	27.4	32.8	
C. (Stock)	4.4	11.8	4.2	5.5	2.4	1.7	35.5	46.7	
C. (Sow)	4.5	12.8	3.8	5.4	2.4	1.9	29.4	41.8	
A.	20.2	10.4	4.2	5.82	2.8	1.3	40.0	55.8	Corpus Luteum
B.	18.1	10.2	2.1		2.3		20.7		
C. (Stock)	2.8	12.9	2.9	3.5	2.8	1.4	22.1	27.4	
C. (Sow)	3.6	13.5	2.8	4.3	0.5	1.3	20.8	31.7	
A.	11.8	11.7	4.9	5.4	1.1	1.3	41.7	47.0	Ovaria Residu
B.	7.6	12.9	2.5	3.0	1.4	1.3	19.0	22.5	
A.	23.3	9.7	4.1	7.0	1.9	1.6	41.0	72.0	
B.	12.1	11.8	2.7	4.2	2.3	2.4	23.0	35.6	Orchic Sub- stances
C.	9.7	11.9	2.5	2.8	2.0	2.0	21.0	23.2	

*The value for each fraction is expressed as parts per 100 by weight in original sample.

However, the clinical test is still the court of the last resort for judging the efficiency of preparations of ovarian and orchic substances. And because of the existing possibility that therapeutic failures may be due to improperly prepared endocrine material it behooves us to study as closely the endocrine product we administer as the clinical condition in which the therapy is applied.

Working in the dark to preserve therapeutic principles of totally unknown chemical properties makes it impossible for one to dogmatically indicate a right and a wrong way of attempting the preservation. We believe, though, that the premise laid down at the outset of this presentation that ideally the aim should be one of preserving everything in the fresh glandular material is thoroughly sound. Judged by such a standard methods of preparation could be comparably evaluated. Such an evaluation for the products herein analyzed would indicate products A as made by the best method.

Historical Medicine

Medicine in the "Good Old Days" *

THE HONORABLE WILLIAM RENWICK RIDDELL, LL.D., F. R. S. C.,
Toronto, Canada

Auber in his interesting *Traité de la Science Médicale,* Paris, 1853, (1) gives an account of twenty-six schools of medicine from the time of Hippocrates down: and he blames the Arabian School founded in the 11th century by Rhazes and Ali-Abbas (2) for "that disgusting polypharmacy so long in vogue among the common people and among physicians . . . follies which had credit of Medicine in the 16th and 17th centuries."

The attribution of these disgusting follies to the Arabian School is unjust; but I do not intend in this paper to discuss the source of these follies—I shall only mention a few of them appearing in a work of vast erudition, a *vade mecum* and book of great authority in its day.

Moses (Moïse) Charas (3) in 1673, published at Paris his *Pharmacopoeia* which appeared in English at London in 1678 under the title *The Royal Pharmacopoeia, Galenical and Chemical Englished.* Louis Guillaume Lemonnier, afterwards one of the (4) Royal Physicians to Louis Quatorze and then to Louis Quinze and Louis Seize (1700-?), published in 1753 an improved edition in French and Latin at Lyons which was translated into all the languages of Europe and even into Chinese—Monnier's edition is in 2 vols., 4to—*Pharmacopée Royale Galenique et Chymique, par Moyse Charas . . . Nouvelle Edition.* I quote only from the first volume devoted to Galenical remedies.

Take this *Pulvis ad partum difficilem,* powder for difficult labor.

℞ *Testiculorum equi in clibano ex arte siccatorum, cinnamomi acuti, nucleorum dactylorum, boracis, croci et foliorum sabinae siccatorum, ana drachm, ij, Trochiscorum de myrrha, drachm, j. M. fiat pulvis* (5).

Or this *Pulvis hystericus,* hysteric powder.

℞ *Verrucarum ad genua equorum nascentium, verno tempore avulsarum, vel sponte procidentium unc. j. Assae foetidae, cornu et ungulae hirci, ana drachm j. M. fiat pulvis* (6).

A much admired antiepileptic oil is made from the following formula:—

℞ *Rasurae cranii hominis morte violentâ perempti, unc. IV. Succini pulverati, unc. VIII. Misceantur in retortâ vitreâ et distillentur igne arenae* (7).

This oil was given internally three to six drops a day for a month: and also applied externally by anointing the inside of the nostrils, the temples and the parts over the sutures of the skull.

The volatile salt of human blood (8) was also used for epilepsy: as was the volatile salt of human urine (9)—this however, was in addition, "highly esteemed in all obstructions of the liver (10), the spleen and the mesentery . . . lethargy, apoplexy. . . . and convulsions . . . difficulties with the urine and even to dissolve renal and vesical calculus."

The oil of human feces "to which some have given the name *occidental civet*" cures erysipelatous ulcers, cancers and sore throat, topically applied.

Vipers furnished many forms of medicine; we find viper soup made of moderately sized vipers and exenterated chickens, viper oil, viper trochees, viper powders, and viper jelly: and vipers are an ingredient in many prescriptions more or less complicated, e. g., d'Aquin's Theriaca in which I count thirty-six ingredients.

Perhaps the prescriptions for the oil and trochees will suffice:

℞ *Viperas viventes magnas, pingues et vividas, No. xij. Olei Communis purissimi, libr. ij. Vini albi generosi, unc. ij. Extrahe oleum s.a.* (11).

This oil is good for all skin diseases including venereal sores—it also facilitates accouchement, *"si l'on en oint tout le ventre."* The oil of serpents is prepared in the same way, and has the same properties but is not so active (12).

For *Trochisci viperini* this is the formula:

℞ *Truncorum, hepatum et cordium viperinorum, in aëre libero extra solis radios siccatorum, quantum libuerit. Fiant ex arte trochisci* (13).

These are sovereign against poisons, serpent bites and all sorts of venomous animals, useful also in malignant fevers, epidemic maladies, etc.

Lizards also have their uses—oil of lizards for increasing the growth of the hair has no superior:

℞ *Olei expressi nucum juglandium depurati, libr. iij. Vini albi, unc. iij. Lacertas viventes, viridcs et vividas, No. xij. vel xv vel xx pro ratione magnitudinis, &c.* (14).

Fox oil, *oleum vulpinum,* is made of a young fox, skinned, exenterated, cut into small pieces and mixed with olive oil and spring water.

This cures rheumatism, sciatica and the like.

Of scorpon oil there are two kinds, *oleum scorpionum simplex* and *oleum scorpionum compositum:* the former is made from live scorpions, olive oil and generous wine; the latter requires no less than five processes and contains in addition to scorpions "captured in the dog days" and olive oil, the leaves, flowers or roots of some thirty-three plants. No wonder then that it is much esteemed against "all kinds of venom and poison, especially . . . the bites of vipers, asps, and all kind of animals and to preserve from and cure the plague. It is also usefully employed against small pox, measles and all epidemic maladies as well as against epilepsy, paralysis and most of the affections of the brain, but particularly against worms and the poison of monk's hood and other aconites."

For hernia, vulgarly called rupture, a plaster of much excellence could be made of fresh eelskin,

*Read before the Toronto Medical Historical Society.

haematite, sugar of lead, burnt tin, gum ammoniac and oil of myrrh.

But the frog had more virtue. Vigo's plaster of frogs with mercury followed this prescription.

℞ *Ranas viventes, No. xij. Lumbricorum terrestrium purgatorum, unc. iv. Radicum ebuli et enulae campanae, ana unc. ij. Schaenanti, staechaids Arabicae et matricariae, ana manip, j. Aceti fortis, vini austeri, ana libr. ij.*

Then another preparation is made from this formula:

℞ *Lithargyri auri praeparati, libr. ij, Pinguedinis porci et vituli, ana unc. ix. Oleorum camomillae, anethi, liliorum, laurini et de spicâ per infusionem et decoctum paratorum, ana libr. s. Cerae citrinae, libr. j. Axungiae viperinae, unc. iv. Pulveris olibani, unc. iij. Euphorbii, unc. js. Croci unc. s. Mercurii vivi, libr. j. Terebinthinae et styracis liquidae, ana unc. iv. Fiat emplastram* (15).

"This plaster appeases pains of the shoulders, arms, thighs, legs and all the solid parts when they arise from any venereal poison for by strengthening the parts it draws out the poison and converts it into a kind of moisture. It is applied also along the spine and elsewhere to eradicate the venereal poison, to provoke the flow of saliva and resolve the nodes and other tumors which form on the legs and on the various other parts of the body." We are not told what function is performed by the frogs.

Perhaps we cannot finish this paper more fittingly than by giving the formula for *oleum lumbricorum*, oil of worms.

℞ *Lumbricorum terrestrium crassiorum lotorum, Olei communis, ana libr. iij. Vini albi, libr. s. Eliciatur oleum* (16).

You gather your worms, hang them for three days to disgorge the earth they have swallowed, wash them well and dry them with a linen cloth—then proceed *secundum artem.*

This oil is used externally for pains in the joints, dressing wounds and bruises, and for all maladies of the nerves and muscles. (17).

Notes.

1. This is one of the most interesting histories of medicine I know of—not so full or so biographical as Bass' monumental work, it is distinctly more philosophical. My quotations are from pp. 132, 170.

2. Mohammed Ebn Zakarijah Abu Bekr, commonly known as Rhazes, born 850, died probably about 925: he wrote no less than 237 treatises, of which his *Aphorisms* is the best known—he was an admirable surgeon and believed in the Oil of Ants. Ali Ben el Abbas, commonly called Ali Abbas, died about 994—his work was translated into Latin by Constantius Africanus under the title Pantegni (i.e. Pantechnai). Those two did not found, but they followed the Arabian School, Auber's *l'Arabisme.*

3. Charas was born in Languedoc in 1618 and followed his profession as apothecary at Orange and later at Paris. Being a Calvinist, he was forced to leave France in 1680—he went to England, then to Holland, then to Spain to attend Charles II. Disputing the contention of the Court physicians, firmly believed in by the Spanish people of the district, that the vipers for twelve miles around Toledo were harmless ever since they had been deprived of their poison by the fiat of a famous Archbishop, he fell into the hands of the Inquisition whence he escaped only by adjuring his Protestantism. He returned to Paris in 1690, where he lived until his death in 1698.

4. Monnier or Le Monnier or more correctly Lemonnier is known only by this work—he modestly hides his identity under initials, describing himself on the title page as *"M. L. M. de l'Académie Royale des Sciences et Docteur en Médecine de la Faculté de Paris."* The work was published *"avec approbation et privilege du roi,"* the Licence being dated seven years before publication, July 15, 1746. He was not yet Royal Physician. See Alfred Franklin's *La Vie Privée d'Autrefois, Les Médecins,* p 169.

5. Of horse's testicles dried *secundum artem* in an oven, highly flavored cinnamon, date stones, borax, saffron and dried leaves of savin, each, two drachms. Myrrh trochees, one drachm. Mix. Form a pill.

6. Of warts growing on horses' knees, taken off in spring or falling spontaneously, one ounce, asafoetida, horn and hoof of the goat, each, one drachm. Mix. Form a pill.

7. Scrapings of the skull of a man snatched away by a violent death, four ounces; pulverized amber, eight ounces. Mix in a glass retort and distil over a hot sand bath. The author calls the *"ignis arende," "à feu de sable augmenté par degré."* He does not personally favor ustion or calcination of the human skull but admits that several authors approve of this form of preparation.

8. Especially *"l'arriere faix des femmes."*

9. Preferably that of "young people who drink wine."

10. "Obstruction" was a blessed name among physicians like "Mesopotamia" among the devout. The celebrated Arnauld de Villeneuve (Arnoldus de Villanova, ob. 1313), giving his pupils practical instructions, recommended that they should under no circumstances manifest hesitation or astonishment. He said (I translate literally). "The seventh precaution is of general application. Suppose that you are unable to understand anything in the case of your patient, say to him with confidence that he has an obstruction of the liver. If he replies that it is in the head or some other part that he suffers, state boldly and positively that that pain comes from the liver. Take great care to use the term 'obstruction' because patients do not know what it means and it is a matter of great importance that they should not know." See his *Medica Practica,* Venice, 1494. A French writer, Alfred Franklin, in his *La Vie Privée d'Autrefois: Les Médecins,* says that the physicians of Philippe le Bel were not of the school of Villeneuve because it is recorded that that King died of a long sickness of which the cause was unknown to his physicians and was *"pour eux et pour beaucoup d'autres le sujet d'une grande surprise et stupeur"*—the fact being that he had broken his leg hunting in the Forest of Fontainebleau when his horse stumbled, and it is said "the troubles of all kinds to which the King was then a prey joined to the attentions showered on them by his physicians had beyond question rendered the sequelae of that accident, mortal.

11. Twelve large, fat, vigorous, live vipers, two pounds of the purest olive oil, two ounces of rich

white wine. Extract the oil according to the rules of the art (*secundum artem*). We are told that the vipers should be captured toward the end of April or the beginning of May, the heads and tails cut off with scissors, the vipers then skinned and all the internal organs taken out except the liver and heart.

12. Charas and Lemonnier do not seem to have approved broth of serpents, which, as all readers of *Salammbo* will remember, was in use among the Carthaginians as a cure for leprosy—nor the flesh of serpents which was recommended by Celsus for food to the mediaeval Knight, Lancinet, as a cure for the King's Evil, *ecrouelles;* where this failed, the faithful Knight was cured by the touch of King Clovis, the first King of France to have the wondrous gift of healing; but, says the jubilant if credulous writer: *"Téousjours despuis, ceste grace et faculté a esté comme héréditaire aux rois de France."* Alfred Franklin's *La Vie Privée d'Autrefois: Les Médecins,* p. 255.

13. Trunks, livers and hearts of vipers dried in the open air in the shade, q.s. make trochees, *secundum artem.*

14. Expressed walnut oil purified, three pounds; white wine, three ounces; lizards, live, green and vigorous, twelve or fifteen or twenty according to the size, &c. This formula is credited to Mathiole, i.e. Pietro Andrea Mattioli (1501-1577) of Florence, a botanist and physician of some note.

15. Live frogs, twelve; earthworms stripped, four ounces; of roots of dwarf elder and elecampane, each, three ounces; of sweet rush, Arabian lavender and motherwort, each, a handful; of strong vinegar and sour wine, two pounds—then of prepared litharge of gold (i.e. ordinary plumbic oxide, PbO, mixed with red lead) two pounds; of pork and calf fat, each, nine ounces; of the oils of camomile, dill, lilies, laurel and spike, prepared by infusion and decoction, each, half a pound; of yellow wax, one pound; of viper fat, four ounces; of powder of olibanum, three ounces; of euphorbium, half an ounce; of saffron, half an ounce; of mercury, one pound; of turpentine and liquid storax, each four ounces. Make a plaster.

16. Of large well washed earthworms and olive oil, each three pounds; of white wine, half a pound. Extract the oil.

17. While our author gives us a few dentifrices, he does not follow *"beaucoup de personnes qui avaient l'etrange coutume de les (dents) nettoyer avec leur urine."* Not so strange—I have known the custom within fifty years in Ontario among certain Canadians of French descent; and I am assured by one who should know that the custom is prevalent among the country people of Normandy.

Against caries of the teeth we are assured by the surgeon B. Martin, author of a *Dissertation sur les dents,* Paris, 1679, p. 64, there are two remarkable specifics *"l'urine et les crottes de chat sauvage."* It will be remembered that John Wesley recommended dry *zibethum occidentale i.e. stercus humanum* warmed and spread on leather as a plaster for "Windy Rupture," ear wax for specks in the eye and goose droppings with celandine as a plaster for Cancer. See *Wesley's System of Medicine,* New York Medical Journal, January 10, 1914.

Contributors to the Science of Medicine

Ambroise Paré

Ambroise Paré was one of the first great surgeons and the first great army surgeon and, as Linacre in England assisted in raising medicine from the slough into which it had fallen through following too closely Arabian precept and practice, so Paré was largely instrumental in combating the Arabian school of surgery and general treatment. Those who did great things for surgery in the Middle Ages may be counted easily on the fingers of one hand. Constantine of Salerno, Guillaume de Salicetis, Lanfranc, Guy de Chauliac and Ambroise Paré, perhaps, for England, John of Gaddesden and John Aderu. The Arabian School, which dominated the practice of medicine and surgery at the time of Paré in France and Linacre in England, had set tradition and authority above observation and experiment. The church, which in France and England and in the other civilized European countries ruled the physicians, forbade the shedding of blood and surgery was kept at the level of badly organized trade. Paré, Linacre and those of a like mind endeavored to overturn tradition and to return to the pure teaching of Hippocrates and Galen. Paré followed the advice of Guy de Chauliac as closely as possible when he wrote, "Let the surgeon be well educated, skillful, ready and courteous. Let him be bold in those things that are safe, fearful in those that are dangerous; avoiding all evil methods and practices. Let him be tender with the sick, honorable to men of his profession, wise in his predictions; chaste, sober, pitiful, merciful; not covetous or extortionate; but rather let him take his wages in moderation according to his work, and the wealth of his patient, and the issue of the disease and his own worth."

Ambroise Paré was a typical figure in many ways of the time and of his country. He contributed greatly to raising the surgeon's profession from a lowly and despised handicraft to a position equal to that of the other branches of the healing art. Paré was essentially an army surgeon, he could hardly escape from being this in the stormy times in which he lived and learned his surgery in the rough and ready school of war. In the year of his birth, 1510, Louis XII was king of France, Maximillian was Emperor, Henry VIII was king of England. During his life the crown of France passed from Louis XII to

Francis I, then to Henry II, then to his three sons in succession, Francis II, Charles IX, and Henry III, and then to Henry III.

In England Edward VI succeeded to his father's throne, then Mary, then Elizabeth. The empire passed from Maximillian to Charles V, and afterwards to Philip of Spain.

During the whole of this time France was at war. Calais was taken from England when Paré was forty-eight. However, the fighting between France and England was nothing to him in comparison with the wars against Germany, Italy and Spain. Other nations were involved, Switzerland and the Netherlands. The King of France in 1548 allied himself with the Sultan Suleiman of Turkey. Italy was invaded several times. The chief enemy against whom he served was the Emperor Charles V, and his son, Philip, of Spain, with their German and Spanish armies and their Italian and English auxiliary forces.

Paré, too, saw civil war when in 1562 France was divided against herself, Catholic against Huguenot.

He lived to be eighty years of age, but the times grew worse as he grew older. At the time of his death things had somewhat bettered. His was a very long life.

Among his contemporaries were Ignatius Loyola, Luther and Erasmus, Calvin and Knox, Shakespeare and Rabelais, Raphael and Titian, Paracelsus, Sirvetus, Sylvius, Vesalius and Linacre. Palissy, the potter, was born in the same year as Paré and the two old men were both in Paris as late as 1559, Paré in his home and Palissy in the Bastile. Paris was besieged by Henry IV in the summer of 1589, the siege was raised on August 29th; Paré died before the end of the year.

AMBROISE PARE

From the original picture in L'Ecole de Médecine, at Paris.

"On Thursday, December the twentieth, the eve of St. Thomas, at Paris in his own house, died Master Ambroise Paré, the king's surgeon, eighty years old, a learned man and chief of all surgeons; who even against the times, all his life talked and spoke openly for peace and for the people; which made him as much beloved by the good as he was begrudged and hated by the wicked."

Ambroise Paré was born in the country in the year 1510. His father was either a worker in wood or a valet and barber. Ambroise had a sister, Catherine, who married a master barber surgeon of Paris; a brother, Jehan, who was a master barber surgeon in Brittany and another who followed his father's trade of chest maker. Little is known of Paré's boyhood except that he never learned Greek or Latin and that he was at Angers when he was fifteen years old. He was apprenticed to a barber surgeon. When he was twenty years of age he was in Paris where the plague was raging. He was given a resident appointment at the Hotel Dieu before he had qualified. Dubois Sylvius was one of his teachers. Andreas Vesalius just missed by a year or two being at the Hotel Dieu with him. Vesalius was born in Brussels, and had been educated at the University of Brussels before he came to Paris to study medicine. He was about three years older than Paré and they both had Sylvius for their teacher. The story that they were opposed in the wars, Paré with the army of the King of France, Vesalius with that of the Emperor, is not probable. Paré's first taste of war was in 1537; and in that year Vesalius was already professor of anatomy at Padua. Probably they met over the deathbed of Henry II in 1559.

It is certain that Paré got plenty of work out of the hospital. He had the charge of patients, the privilege of making dissections and postmortem examinations. In one winter he operated in four cases of loss of nose from frost bite; he witnessed the terrors of the plague; indeed, he wrote a book on it, and took part in the whole practice, outpatient and inpatient, of the hospital.

In the year 1537 he was appointed surgeon to the Marechal de Montéjan, colonel general of the French infantry, who were marching under the Constable de Montmorency, to recover Piedmont and Savoy for Francis I from the forces of the Emperor Charles V. It should be understood that at that time there was no organized army medical service. The king took with him his own physicians, who were priests. The seigneurs had their own physicians, priests or clerks in holy orders, who also served as chaplains to the army. A host of barber surgeons and irregular practitioners and quacks of all kinds followed the troops with drugs and ointments and Arabian remedies, women skilled in sucking and dressing wounds went in and out of the camp, while the soldiers, of course, had their own rough and ready methods.

Paré then had no recognized position in the army, no rank in the camp. However, after the first battle he found his hands full with work for which he was wholly unprepared. At first like the other surgeons he followed the rule of Vigo and treated all gunshot wounds with boiling oil. The theory then was that gunshot wounds were poisoned and the boiling oil was considered necessary to drive out the poison. One evening, his supplies of oil having run out, he was compelled to treat his patients without it. The next morning he was astonished to find that every man whose wounds had been treated with a salve only had passed a comfortable night; while all those who had undergone the customary treatment were in fever and great pain. Paré never used boiling oil again.

When his patron, Montejan, died in 1538 Paré returned to Paris and continued his studies and in 1541 was admitted a Master Barber. In the same year Paré married and barely twelve months after was off to the wars again, this time in the service of M. de Rohan. Paré's field surgery was again very successful.

During the intervals of his campaigns Paré practised as an ordinary barber surgeon in Paris. Stimulated by the encouragement of his old teacher Sylvius, Paré published in 1545 the first contribution to surgical literature on gunshot wounds, and also became prosector to Sylvius. In 1550 he published a short book on anatomy and in 1552 a second enlarged edition of his work on gunshot wounds, with much additional material on bruises, burns and gangrenes. Paré was beginning to make for himself a great name. His next chief was the Duc de Vendome, King of Navarre, who, on his return to Paris after a victorious campaign, presented Paré to Henry II, who appointed him one of his surgeons.

War again broke out and Paré was dispatched to Marshal St. André at Verdun and eventually was captured by the enemy and as a reward for his successful treatment of a distinguished enemy general was accorded his liberty. At this time Paré, who had now become, perhaps, the best known surgeon in France, was promoted from the status of "Master Barber Surgeon" to that of "Sworn Master Surgeon of the Brotherhood of St. Cosmas." The succeeding years were filled for Paré with the practice of the profession and with voluminous writings. He was appointed surgeon to the successive occupants of the French throne. Between 1560 and his death in 1590 Paré published or republished twelve volumes.

Among other surgical procedures concerning which he wrote was that of cutting for stone and the surgery of the urinary and genital organs. He wrote a book on gout and another on poisons and bites. As said before, he wrote on the plague and in fact there were few subjects in connection with surgery or even medicine that he did not discuss in writing. Paré was not, perhaps, an original genius, but he was the embodiment of that insatiable curiosity with regard to his own science which has distinguished all great pioneers and reformers. His great contributions to surgery were his discovery that the best treatment for gunshot wounds was not boiling oil but rather soothing applications.

The doctrine that hemorrhage after amputations should not be arrested by the terrible cautery but by simple ligature, and lastly his advocacy of the method now known as podalic version of the babe before delivery in cases of abnormal presentation.

His efforts were always exerted to overthrow the long standing Arabian domination of medicine and surgery and to assist in the return to methods advocated by Aristotle, Hippocrates and Galen. He raised the position of surgeons immeasurably and by his example and precept was a beacon light to the surgeons of his day and succeeding generations. Stephen Paget in *Ambroise Paré and His Times* suggests that in his methods of work Paré resembled in some ways John Hunter. They both of them began life in the country; they saw war and wrote on gunshot wounds; they spent money lavishly when it came; they were both great lovers of animals and their ways. Paré like Hunter loved the collecting of specimens, dissecting them and demonstrating them, although Hunter's magnificent collection is far beyond anything that Paré dreamed of. Yet Paré was diligent at the same work; his house was full of curiosities of natural history and surgery. He gets a rare specimen of disease and calls together sixteen physicians and surgeons to see him dissect it. He gets a dead ostrich and makes a skeleton of it. He keeps the bullets he has removed and shows odd specimens at Court. But there were two points of special likeness between these two great men, their extreme inquisitiveness. They were not satisfied until they had got at the root of a question as far as they were able. They constantly appealed to experiment, questioned, compared notes, getting to learn the results obtained by other men. Paré carried out Hunter's dictum, "Don't think, try."

Paré's influence on surgery was really remarkable. During his lifetime many of the Italian and French great surgeons and physicians adopted his views concerning the nonpoisonous nature of gunshot wounds and revised their mode of treatment accordingly.

Perhaps the greatest of all his contributions to medicine, points out Mrs. Singer in her recent work on Paré, was the service of his own winning personality, the example of his steadfast efforts to increase his knowledge of human anatomy and his skill in the surgical art, and his constant emphasis on the surgeon's duty to exert his utmost efforts to avoid or relieve the patient's sufferings. He was a man of infinite humanity; one of the last and greatest acts of his life was to denounce to his face the Archbishop of Lyons for the harsh measures he recommended for the starving populace of Paris during its siege by Henry IV. To him might be aptly applied the sketch of ideal medical man as conceived by Robert Louis Stevenson, "Generosity he has, such as is possible to those who practise an art, never to those who drive a trade; discretion, tested by a hundred secrets; tact, tried in a hundred embarrassments; and what are more important Heraclean cheerfulness and courage. So it is that he brings air and cheer in the sickroom, and often enough, though not so often as he wishes, brings healing."

Sunlight Therapy.—In or before the eighth century B. C., says Dr. C. W. Saleeby in *Sunlight and Health*, Zarathustra, foremost among sun worshippers, taught the cult of the sun and the green leaf and thrift, in place of pillage and murder. In the beginning of medicine, Hippocrates, practising at Cos, in the Temple of Æsculapius, son of Phoebus Apollo, god of the sun and music, practised the sun cure. In the beginning of our era, Galen and Celsus used the sun.

In 1893, says Dr. Saleeby, Niels Finsen began to cure lupus by the local use of sunlight, and Sir James Crichton-Browne made observations to the same effect in England. In 1900, on May 1st, the London Hospital began the cure of lupus by the local use of sunlight, thanks to Queen Alexandra who was instrumental in bringing her young fellow countryman's idea from Copenhagen.

THE DISTRIBUTION OF DOCTORS

The General Education Board has just published a report of a study of the distribution of the physicians in the United States made by Lewis Mayers and Leonard V. Harrison. The study was inspired by the occasional cry that goes up of a scarcity of physicians in rural communities. As mentioned in these pages, this state of affairs is oftentimes more in the nature of a theory than a fact, and the cry for a doctor is not infrequently made by a few persons who are disgruntled with, or have not paid the bills of, the physician who is on the spot. Sometimes the call for a doctor comes from some family from the city who finds the resident practitioner not quite sufficiently polished to suit the new resident, though from the very nature of country practice (which is an education in itself) he may be much more capable than the average doctor in the city from whence the new resident comes. The very fact that a doctor practises in a larger place lends a halo of efficiency to his actual capacity.

The report says: "There are today undoubtedly some hundreds of such villages without a physician. The apparent reason, in nearly every case, for the failure of the village to attract a physician, the reason indeed, in many cases, for its having lost the physician it once had, is that despite its being the natural centre of an area populous enough to give wholly adequate support to a physician, a physician locating there could not be certain of even a bare living; a substantial portion of the medical work of the area, and a still more substantial portion of the income, goes to the more distant yet wholly convenient town (in not a few cases, as already suggested, the physician who formerly practised in the village is now located at the adjacent town and his hold on his former territory is likely to be especially tenacious); so that a practitioner in the village would find his income hardy less precarious, and his professional position much less satisfactory, than the village practitioner located in a much poorer, but more remote, area. There exist the apparent need and the apparent ability to support; but the two are not correlated in such a way as to yield any assurance that the individual practitioner who attempts to meet the need will receive the support."

"Summarizing, it appears that a substantial proportion of villages said to be in need of a physician cannot, under the régime of modern transportation, be considered as the logical exclusive centre of an area sufficiently large to utilize the entire time of a physician, and are situated in territory which is already covered from surrounding villages. A small number of remote areas sparsely settled but populous enough to require the entire time of a physician have not, owing to extreme poverty combined with extremely unattractive conditions, a resident physician but must depend for medical service on towns unduly remote, whose physicians are already fully occupied nearer home. A considerable number of rural areas fairly remote from a town, and of the prosperous kind, but well above the pauper level of the areas just referred to, appear to have an unduly low proportion of physicians to population, but are wanting in any particular village, now without a physician, in which a physician locating would have a reasonable assurance of earning a good living. Finally, there is a considerable number of villages in the more prosperous rural areas, now without physicians, which though located within accessible distance of a larger town, are logical and desirable locations for a physician, provided he could be assured of the patronage of the people for whom the village forms the natural centre.

"Our review of the situation has thus led us to the conclusion that only in comparatively few cases do the vacant locations apparently in need of a physician offer any reasonable assurance of a livelihood obtainable within a reasonable time; and that in the cases where such assurance is possibly present, the livelihood obtainable is frequently too meager to offset the extreme conditions of isolation and hardships found in those areas."

That a community of five hundred people could easily furnish a living to a physician is evidenced by the fact that if each paid him two cents a day (less than will be spent for candy and cigars) he would have an income of $3,500. If this amount were paid as a bonus or for annual health examinations, he might do very well indeed with moderate extra fees for sickness and childbirth. We are quite willing to pay out more money for useless or harmful luxuries than for the preservation of, or even restoration to, health.

The report finds that the essential cause of migration of physicians to larger centres is chiefly the superior social advantages and to escape the hard physical work of long drives over bad roads.

In the cities the general population cannot afford to be sick and, in the rural regions, it looks as if they would be compelled to obey the laws of health.

The report ends with the following paragraph:

"If the conclusions reached in the present chapter are sound, no reduction of medical school require-

ments, either for entrance or graduation, that is at all within the realm of possibility, would be likely to have a significant effect upon the future supply of physicians to the rural areas; and the creation of a substandard class of physicians for those areas is quite impracticable. Whatever may be thought, therefore, of the necessity for taking measures to meet the problem of rural medical service, it seems clear that the situation does not call for any present action in the field of medical education in the direction of a reduction in requirements or a lowering of standards."

THE SECRET OF CARIES

It looks as if the causes of dental caries were near being discovered, and, with it, the means of partial or total prevention. If it comes to pass that this most common of diseases can be greatly reduced, there will be an enormous saving in cash as well as improvement in health, for our dental bills run somewhere in the hundred millions, although a large percentage of carious teeth go uncared for and rot away until they fall out or are removed because of pain.

Dr. May Mellanby has done a fine piece of work in the study of the effects of foods on the dental conditions of dogs, and she found that both the structure and arrangement of teeth in puppies depend on their diet and environment during the period of tooth development. Some foods help, some hinder, dental development. Materials to be found in codliver oil, animal fats (except lard), milk and yolk of egg are especially useful, while the feeding of cereals, especially oatmeal, leads to badly formed teeth peculiarly subject to caries.

Exposure to either sunlight or to ultraviolet rays "has, under some conditions, an important influence on tooth formation . . . probably by making active the calcifying vitamine stored in the body. . . . In fact, the interaction of dietetic and environmental influences on teeth formation is certainly very close."

Dr. Mellanby finds that "teeth may be well formed and yet be likely to become carious" though, on the whole, well formed teeth are the least carious. In well formed but carious teeth the secondary dentine present was usually found to be poorly calcified, while in badly formed teeth, free from caries, or in which caries had been arrested, there was generally some well formed secondary dentine.

Mellanby, Pattison, and Proud are carrying out some experiments on the effects of these various conditions on children, in a London hospital and, considering the length of the experiment, their findings are most interesting. Three groups of children were used, all of them between seven and seven and a half years of age. One group was placed on a diet which included codliver oil, from two to one and a half pints of milk, and eggs, but no oatmeal. The second group were given a similar diet, though with little milk, little egg, no codliver oil, but with oatmeal. The third group had the regular hospital diet. All had fruit, potato, and other vegetables, meat, bread, rice and sugar. The first group received butter; the others, oleomargarine. The average number of carious teeth for the groups at the beginning was 6.5, 6.125 and 7. The average increase of old caries was .75, 2.3 and 1.4. The average new teeth becoming carious was .65, 2.8 and 1.54. The average new and increase of old caries was 1, 5.1 and 2.9.

It would be most instructive if the experimenters could continue this experiment on the same groups of children by changing their diets, and reversing that of the first and second.

SYPHILIS OF THE THYROID GLAND.

As pointed out by Dr. Guillaume in his article which appears in this issue, syphilis of the thyroid is a rare affection. The secondary manifestations—specific thyroiditis—may terminate in exophthalmic goitre, as Schulmann has shown (Medical Journal and Record, September 17, 1924). Pathologically, tertiary thyroiditis presents itself in one of three types, namely, the gummatous, sclerogummatous, and sclerous. In the sclerogummatous type, lesions of the trachea are always present, and would appear to indicate a primary specific localization in the trachea and larynx, finally ending in a cervical cellulitis which surrounds and secondarily compresses the thyroid, but this point is not as yet perfectly clear and further study is necessary.

Histologically, none of the elements described—round cell infiltration, sclerosis, gummata, epithelioid nodules, giant cells, and vascular changes—can be regarded as specific. These lesions are quite likely to be mistaken for tuberculosis or certain types of sarcoma. Clinically, the circumscribed gummatous type simulates nuclear goitre and cyst of the thyroid, while the sclerogummatous and ligniform types are quite identical with cancer and Riedel's disease. The sclerous type is quite impossible to diagnose clinically, but the nature of the gummatous form may be suspected by the hardness and irregularity of the tumor and its sensitiveness to deep palpation. Hence, in practice, when in the presence of a thyroid neoplasm, it is absolutely essential to search for syphilitic lesions in the patient's antecedents and resort to the Bordet-Wassermann test. If one is still in doubt, a test treatment should be essayed.

The prognosis of the gummatous form is good.

In the sclerogummatous and ligniform types the lesions of the larynx and trachea dominate the evolution of the process and may cause sudden death, hence the necessity of laryngoscopic examination.

As to treatment, potassium iodide, mercury, and arsenic will cause the tumor rapidly to disappear. In the sclerogummatous and ligniform types with lesions of the trachea and larynx a combined mercury and arsenic treatment is indicated, and will avoid the necessity of a useless surgical interference. But should asphyxia be imminent, palliative tracheotomy must naturally be done.

INTRACRANIAL ABSCESSES

Intracranial abscesses may be either extradural or intradural; the former develop between the skull and dura, the latter in the cerebral substance. Meningeal abscesses are exceptional. Intracranial abscesses, excepting those of traumatic origin, occasionally result from suppurating processes in the sinuses, but in the immense majority of cases they follow some otic infection, and in spite of their relative frequency they are generally unrecognized. Undoubtedly this is due to the fact that they are seated in the temporosphenoidal lobe or the external aspect of the cerebellum, these areas giving rise to relatively few symptoms and regardless of rather extensive destructive lesions sometimes observed, their symptomatology is latent.

A brain abscess when fully developed and up to the appearance of coma is an ambulatory affection. The loss of consciousness often appears to be the initial symptoms of the process, but in reality such is not the case because a diagnosis can be made earlier in the evolution of the disease. There are two symptoms which from their permanence and constancy are undeniable signs of an intracranial abscess, especially the most serious form, namely, an intracerebral abscess. These signs are almost pathognomonic and may be met with singly or combined with the following symptoms, viz., a slow pulse, hypothermy, vomiting, papillary stasis, pain on pressure, and localizing signs, but the latter are uncommon.

The two pathognomonic symptoms are headache and intellectual dullness with psychic depression; at an advanced phase of the process somnolence, stupor, etc. Hence it is the initial symptoms that are to be searched for in order to act both usefully and without delay, before the patient is bedridden and the major cerebral lesions appear. All the other signs that have been described—and they are numerous—are of secondary importance.

It is true that headache and intellectual dullness also are met with in aseptic hypertensive meningitis but in these circumstances they are much more ac centuated, the patient complaining of violent pai in the head and other symptoms. A patient wit abscess refers indifferently to pain; he is in a stat of torpor from which he is with difficulty arouse and then he will be quite indifferent regarding hi condition.

As to the usual classical signs of brain abscess an their diagnostic value it can be said that hypotherm is met with when the pus is encysted, while ther is a rise of temperature when diffuse encephalitis o an inflammatory reactional meningitis exists. Papil lary stasis is the result of a superadded meningea reaction, but a slow pulse is more important and i not infrequent. To possess all its value the follow ing conditions must be realized, namely, drainage o the bone lesions and absence of septic absorption an inflammatory meningeal reaction. For that matter during the evolution of a brain abscess there may b hypothermy or fever, a slow or rapid pulse, and ever dissociation of the pulse and temperature. Moto symptoms are unusual. Hence the two most im portant symptoms of brain abscess—because they are constant and occur early in the evolution of th process—are headache and intellectual dullness wit a change of character.

MUSIC AS A MEDICINE

A poet once said that music hath charms t soothe the savage breast and the soothing influence of music has been referred to by distinguished writers on many occasions. Recently, more than one writer has urged that music under certain conditions exerts definite remedial powers. Not long ago a British writer extolled the healing effects of music both on the body and mind diseased and now under the aegis of the American National Bureau for the Advancement of Music Mr. Willem van de Wall has published a book, *The Utilization of Music in Prisons and Mental Hospitals.*

Mr. van de Wall, who was at one time harpist in the orchestra of the Metropolitan Opera, has had much experience as a student of mental cases. It may be interpolated that the most celebrated instance from history of mental aberration being overcome by music is that of King Saul, who was charmed into a normal state by the playing on the harp by David. Indeed, in old times when it was the current belief that insanity signified that the person afflicted was possessed of an evil spirit, it was also the belief that music sometimes had the power of driving out the evil spirit. Mr. van de Wall seems to show in his book that great benefit may be derived from music by those mentally unbalanced and even in cases which have appeared incurable.

He does not claim so much for music in itself but recognizes that its chief good generally comes from the fact that it takes the patient out of himself and discourages brooding and introspection, the main banes of one demented. Mr. van de Wall states that in his opinion "music is the most efficient general disciplinarian and moral agent in prison management, effecting at once that for which modern, humane and sensible imprisonment is intended, namely, the change of bad feelings into good, the doing of friendly deeds rather than evil, the substitution of constructive habits for destructive." If it be granted that the criminal is a criminal because he is possessed of an abnormal mind and that music will do much for his moral regeneration, and that music exercises distinct therapeutic effects on those of obviously unbalanced minds, what may not music do in preventing mental and moral aberrations.

Mr. van de Wall holds that music may exert an excellently beneficial preventive action. In fact, he insists that in certain circumstances music may be either preventive or curative. There may be exerted and doubtless is exerted by music a good mental and moral influence and provided that many of the occupants of an institution for the insane are not musicians themselves, the effects of music may be remedial. But unless the music is of a high standard it is not unlikely that really musical inmates may be driven to an acute and violent stage of madness rather than soothed and taken out of themselves by the entertainment provided for them.

An inmate who knows little or nothing of music is more likely to be favorably influenced by a band as described by Mr. van de Wall consisting among other instruments of six trombones, ten saxophones and just a bunch of clarinets and cornets, than one whose ear is attuned to sweet musical sounds by experience and perhaps by heredity. Is music then preventive of an unhinged mind, and is it essentially a harmonizer?

The history of the lives of great composers, players and singers seems to be opposed to such a statement. As a rule, musicians themselves and those who have to do with music are not remarkable for their suavity, urbanity, or are not conspicuous for their personal and social virtues. If the tales told of them be true or partly so, they are in the main by no means a harmonious company but stand out from the ordinary individuals who comprise the community as especially selfcentred, vain, selfwilled and jealous. Again as a preventive measure music would be most difficult, indeed impossible, to prescribe. To whom or to which class should this unenviable task be delegated?

So far as music as a preventive measure is concerned it may be concluded that its practical application is not feasible. As a remedial measure in some conditions it has its good points. In a State institution, the inmates can be controlled and "the proper application of music" may be followed by satisfactory results.

Music may be likened in some respects to food—"what's one man's meat is another man's poison." The Scotchman has a partiality for coarse oatmeal, haggis and the bagpipes, while such harsh food and music would be displeasing to most Italians. However, there is truth no doubt in the assertion that music has often a favorable influence on morals and mind and certainly stirs the emotions and deters for a time, at any rate, introspection.

THE ADVANCEMENT OF SCIENCE

"It is a wonderful thing," said President Coolidge in his address before the American Association for the Advancement of Science at its recent meeting in Washington, "to live in a time when the search for truth is the foremost interest of the race. It has taken endless ages to create in men the courage that will accept the truth simply because it is the truth. Ours is a generation of pioneers in this new faith. Not many of us are endowed with the kind of mental equipment that can employ the scientific method in seeking for the truth. But we have advanced so far that we do not fear the results of that process. We need truth; and we turn to you men of science and of faith, eager to give you all encouragement in your quest for it." In this statement President Coolidge doubtless voices the belief of most of the thinking minds of this country, with all due respect to the truth of the fact that science in the hands of the evil or unscrupulous may become not only a menace but a real danger. Yet this is a risk that is always coincident with progress, and is perhaps today no greater than in former times.

The annual meeting of the American Association for the Advancement of Science was marked by an unusual number of significant papers and addresses. Among these was the report on mercurochrome, the general antiseptic against most forms of bacteria, by Dr. Hugh P. Young, of Johns Hopkins University. Mercurochrome was produced at the Brady Urological Institute, and is administered intravenously and otherwise. Dr. Young predicted that this drug will doubtless bring about the greatest conquest of disease in the history of medicine. In the investigation 265 different chemical combinations were worked out and studied for their effects. Mercurochrome was found to be the most efficacious in its germicidal properties as well as in its lack of harmful sequelæ. The drug has been used successfully in treating septicemia, advanced pneumonia and

many kinds of focal infections, and has been tried in the treatment of many other kinds of acute and chronic infections and infectious diseases.

Among other significant papers was that of Dr. Morton C. Kahn, of Cornell University Medical School, in which he described the findings of the Bacillus welchii, an organism discovered by Dr. Welch of Johns Hopkins, in the intestinal tracts of patients suffering from pernicious anemia, and the possibility of their being a causative factor in the disease. Dr. William A. Noyes, who has recently returned from an extended European tour, read a paper on European laboratories in which he emphasized the great work being done there in spite of depreciated currencies and high costs of living consequent upon the war. Dr. George Sarton, of the Carnegie Institution, presented a paper on medieval science to the history of medicine section of the meeting.

PSYCHOLOGICAL TESTING

The greatest impetus that has ever been given to mental or psychological testing came through the world war. After discussing the origins and principles of mental testing, and outlining the Army tests, Helen B. Dolan, of the United States Public Health Service, writes in a recent number of *Public Health Reports* about developments since that period. It was during the war that the alpha and beta tests were organized and successfully applied. Up to the close of the war work had been done along lines of testing general intelligence only, but with the development of the Army tests, many new possibilities were opened up, and psychologists enthusiastically undertook to broaden the field and extend its limits. Trade tests and tests rating special abilities were organized, the number and kinds of intelligence tests were increased, and finally attempts have been made to measure temperamental characteristics. None of these latter tests, however, have been standardized, and so cannot be rated as giving a definite measurement of the trait under consideration. Many of them take the form of single trait measurements, such as aggressiveness, social relations, selfassurance, speed in the ability to make decisions, and creative imagination. The Downey will temperament test, while still questionable, for various reasons, as to its results, represents an attempt to obtain an appraisal of temperamental qualities. It comprises twelve tests, each measuring a certain personal characteristic of the individual being tested. Through this test, individuals may be classified roughly in three types: the explosive; the willful, aggressive; and the slow, accurate, tenacious types. It has been considered that a high total score tends to indicate a strong personality. The tests for creative imagination, esthetic judgment, and moral concepts are still so elementary and lacking in scope that they seem hardly practicable or significant in their results.

In foreign countries, interest in psychological testing seems not to be so widespread as in the United States, although France has given considerable attention to vocational guidance for exsoldiers. In that country also American methods of industrial management are beginning to be used. England is interested in job analysis and is attempting to ameliorate industrial conditions through vocational guidance. Germany has a national association for vocational guidance, and in some of the cities occupational tests are given in factories and intelligence tests to school children. The article states, however, that these are poorly administered. In China the first attempt to introduce scientific intelligence tests was made in 1920 by two Chinese psychologists who had been educated in America. The fact that so many of the Chinese are illiterate made these tests applicable to very few, so efforts are being directed to devising nonverbal tests for use there.

The process of developing mental tests has laid stress upon the quantity of the tests at the expense of their quality. As a result, the real problems of securing accurate measurements were not realized until analyses were made of the quality and reliability of the tests already in existence.

News Items.

Tropical Disease Study.—The United Fruit Company offers a limited number of passes for properly accredited scientific investigators who wish to work at the Barro Colorado Island Research Laboratory, in Panama. Applications for passes should be addressed to Thomas Barbour, Ph.D., in care of the National Research Council, Washington, D. C., or to the Museum of Comparative Zoology, Cambridge, Mass.

Personal.—Dr. Robert A. Lambert, professor of medicine at the Sao Paulo Medical School, Brazil, and connected with the Rockefeller Foundation, has returned to this country.

Dr. Arnold Messing has received an appointment as adjunct assistant surgeon to Gouverneur Hospital, New York.

Dr. J. M. Gershberg, who has been abroad for fourteen years, is to resume his practice in New York.

Dr. Luis P. Berne has received an appointment as consulting plastic surgeon for the Rockaway Beach Hospital.

Dr. Wendell C. Philips, who is retiring from active service at the Manhattan Eye, Ear, and Throat Hospital, will be the guest of honor at a dinner given on February 7th, by present and former members of the staff.

Dr. Frank Billings, of Chicago, has been elected an honorary member of the American Stomatological Society.

Dr. George Draper, of New York, spoke on the "Relation of the Human Constitution to Disease," and Dr. Alfred F. Hess, on "Recent Advances in the Biological Effects of the Ultraviolet Rays," at the meeting of the medical section of the American Association for the Advancement of Science held in Washington during the week of December 29th.

Dr. Cornelius G. Coakley, of New York, has sailed for France, to deliver a course of lectures before the International Postgraduate School at the St. Louis Hospital, Paris.

Canadian Social Hygiene Association.—A grant of fifteen thousand dollars from the Metropolitan Life Insurance Company has been made to the Canadian Social Hygiene Association, for aid in extending its child welfare and educational activities.

New Medical Centre.—Ceremonies connected with breaking ground for the new medical centre of Columbia University and the Presbyterian Hospital were held Saturday afternoon, January 31st, with General William Barclay Parsons, chairman of the joint administrative board, as presiding officer. Addresses were made by Nicholas Murray Butler, Dr. C. Floyd Haviland, Mr. Dean Sage, and the ground was broken by Mr. Edward S. Harkness, first chairman of the board.

Tryparsamide to Be Placed on Sale.—The Rockefeller Institute for Medical Research has announced the release of the drug known as tryparsamide for use in the treatment of human and animal trypanosomiasis (African sleeping sickness and *mal de caderas*) and selected cases of syphilis of the central nervous system. This action is based on results reported from clinical investigations which have been in progress for several years. In releasing the drug for the benefit of the public, the Rockefeller Institute desires it to be known that the institute does not share in any way in profits that may be derived from the sale of the drug, and that, with the cordial cooperation of the manufacturers, provision has been made for the maintenance of a schedule of prices on as low a basis as possible.

Benefit for Needy Physicians.—The Association for the Relief of Needy Physicians of Central and Eastern Europe, is asranging a benefit performance of "Artists and Models," on Monday evening, February 9th, at the Astor Theatre, Broadway and Thirty-ninth Street. Contrary to popular belief that with the adoption of the Dawes Plan and the stabilization of the mark, conditions are such that no further help is need, many of the older physicians, men whose names are world famous, are still facing actual starvation. Even more deplorable are the conditions of the windows and orphans of physicians; the aged daughter of Prof. Rudolf Virchow has become a charity ward of the city of Berlin. Medical men of Germany have raised the sum of 300,000 gold marks for the widows of their colleagues, in spite of the fact that a busy physician earns about sixty-five marks a month, or a little over $15 in American currency.

International Congress of Radiology.—It has been suggested that an International Congress of Radiology be held in London in the summer of 1925. The date proposed for the opening is Tuesday, June 30th, the congress to occupy four days of two sessions each, with subsequent visits to provincial centres. The house of the British Institute of Radiology will be used as an administrative and social centre for the Congress. It is hoped that an International Committee will be formed by a number of leading radiologists throughout the world and that the congress will serve to initiate at the institute a permanent nucleus for international collaboration on radiology and kindred subjects. The provisional committee charged with the preliminary arrangements will meet in London early in September, when it is hoped that it will be possible to draw up a definite program and fix the date.

All communications should be addressed to The Secretary, International Congress of Radiology, c/o The British Institute of Radiology, 32 Welbeck Street, London, W.1.

Hospital News.—St. Francis Hospital, New York, is building a forty-room nurses' home. The Newark City Hospital is building a convalescent hospital on a hundred acres of vacant land near the Newark City Almshouse.

The New York Association for the Blind is planning a new building, to cost $250,000, on the site of its present Lighthouse, and on the next lot on Fifty-ninth Street.

The Brooklyn Nursery and Infants' Hospital has completed a campaign for raising $45,000 as an emergency fund.

The Flower Hospital, of New York, makes an announcement of special courses in blood transfusion and blood perfusion, under Dr. A. L. Soresi, director of surgical research. Indigent patients will be treated Wednesdays for blood transfusion or perfusion, and on Thursdays for empyema.

The Massachusetts General Hospital announces that its surgical services will be reduced from three to two. Dr. Daniel F. Jones and Dr. Edward P. Richardson will serve as chief, with Dr. Charles A. Porter as surgeon in chief of both services.

Books for the Blind.—The Permanent Blind Relief War Fund, 730 Fifth Avenue, New York, announces several English books in Braille, and between forty and fifty French titles. These are for distribution to libraries with departments for the blind, requests for the war blind being given preference.

Public Health Expenditures.—The Conference of State and Provincial Health Authorities of North America has tabulated expenditures for public health administration work. New York State stands eleventh in the list, spending 14.0 cents per capita. Heading the list is Delaware, with an expenditure of 39.2 cents, and Massachusetts comes next, with 27.9 cents, followed by Pennsylvania, with 25.9 cents.

New Hospital for Indiana University.—Mr. and Mrs. William H. Coleman, of Indianapolis, have given $250,000 to Indiana University for a woman's hospital, principally maternity cases, to be located on the medical school campus, and to serve as a training unit for the school of medicine. The hospital is a memorial to their daughter, Suemma Coleman Atkins. There will be accommodations for about one hundred patients.

Society News.—The Mercer County Medical Society, at a meeting at Trenton, New Jersey elected the following officers: Dr. Daniel L. Haggerty, president; Dr. John B. Comfort, vice-president; Dr. Alfred D. Hutchinson, secretary, and Dr. Harry R. North, treasurer.

A conference on tuberculosis was held in Pittsburgh January 20th and 21st, under the auspices of the Pennsylvania Tuberculosis Society, marking the thirty-third annual meeting of the society.

Caduceus Post, No. 818, American Legion, composed of some five hundred medical officers of the world war, has elected the following officers: Commander, Dr. Graeme M. Hammond; first vice-commander, Dr. Jay D. Whitham; second vice-commander, Dr. Herbert L. Wheeler; third vice-commander, Col. F. F. Reynolds; adjutant and treasurer, Mr. Robert R. Gerstner.

The Medical Officers' Association of the U. S. Veterans' Bureau, New York City Office, has elected the following officers: President, Dr. Emil Boehm; vice-president, Dr. G. C. Colyer; secretary-treasurer, Dr. Charles R. Brooke.

The New York Physicians' Association has elected the following officers: President, Dr. Jacob Braun; first vice-president, Dr. Leopold Marcus; second vice-president, Dr. Joseph Ziporkes; treasurer, Dr. Aaron Brown; secretary, Dr. James W. Smith; recording secretary, Dr. Max Soletsky; trustees, Dr. Arnold Sturmdorf, Dr. Arthur E. Hoag and Dr. Alfred E. Hellmann.

The American Laryngological, Rhinological and Otological Society has completed arrangements for its 1925 convention which it will hold at The Ambassador Hotel, Atlantic City, May 22nd to 25th. The American Proctologic Society and the Association for the Study of Internal Secretion will also meet at that hotel directly following.

The Riverside Medical Society of the City of New York elected the following officers for 1925 at its recent meeting: Dr. Isador Kahn, president; Dr. Michael Schuman, vice-president; Dr. Samuel Morse, secretary; Dr. Louis Lewis, treasurer.

At a meeting of the Metropolitan Medical Society, held December 23d, the following men were elected to office for the ensuing year: President, Dr. Louis Carp; vice-president, Dr. Joseph Felsen; treasurer, Dr. Morris Grossman; recording secretary, Dr. Theodor Blum; corresponding secretary, Dr. I. Morton Brenner; executive committee member, Dr. S. Philip Goodhart.

The Indiana State Medical Association has elected the following officers: Dr. Eldridge M. Shanklin, Hammond, president; Dr. Charles G. Beall, Fort Wayne, Dr. John H. Hare, Evansville, and Dr. Melville F. Johnston, Richmond, vice-presidents; Dr. Charles N. Combs, Terre Haute, secretary-treasurer; and Dr. Joseph Rilus Eastman, Indianapolis, as delegate, and Dr. David Ross, Indiapapolis, as alternate delegate to the American Medical Association.

The Maine Public Health Association has elected the following officers: Mr. Henry Richards, Gardiner, president; Dr. Elmer D. Merrill, Dover-Foxcroft, honorary president; Dr. Bertram K. Brayant, Bangor, vice-president; Mrs. Sarah Rideout Abbott, Saco, second vice-president; Judge Benjamin F. Cleaves, Portland, third vice-president; Mrs. J. H. Huddleston, Orono, secretary; Mr. Arthur Tiffin, Augusta, treasurer.

Foreign Correspondence.

LONDON LETTER

(From our own correspondent)

London, *December 17, 1924.*

NEW HOUSE OF COMMONS AND PUBLIC HEALTH

It was the conservative Disraeli who said that the first aim of a statesman should be to ensure as far as possible the good health of the people of a country, and the Government now in power appears to be about to act up to the teachings of one of its most distinguished leaders and to take steps in two directions to maintain public health at a high standard. The most important health question of the day in all civilized countries, and especially in an industrial overcrowded country as Great Britain is, is that of housing. In the cities and towns large and small there are slum areas highly prejudicial to health, while the character of the houses in some rural districts is distinctly bad. Moreover, there is a grave insufficiency of houses throughout the country.

It is therefore encouraging to know that the Minister of Health, whose department is responsible for the building of houses, is an able, practical man who has had experience already as Minister of Health. Mr. Neville Chamberlain is a son of the late Joseph Chamberlain, a statesman who enjoyed perhaps the confidence of the country to a greater extent than any public man of his time. Mr. Neville Chamberlain was trained in the same school as his father was, in the municipal government of the largest provincial city of England, Birmingham, which on account of the wise organization and management of its municipal affairs is regarded as a model. Mr. Neville Chamberlain promised to be a success during his too brief first term of office, and it was at his own request that he became again the director of housing operations in Great Britain. Given a free hand and provided that he is treated with fairness by master builders and workers Mr. Chamberlain is more likely to solve the housing problem successfully than anyone and thus may prove the greatest factor in the progress of preventive medicine of this generation.

SMOKE ABATEMENT IN GREAT BRITAIN

Another advance towards a high ideal of public health is to be made in respect of smoke abatement. Owing to the humid atmosphere of these islands and the vast and careless consumption of soft coal, the large cities of this country are cursed with more than their fair share of polluted air. Indeed, at this time of the year the consequences of this disability are frequently strikingly exemplified. During the past week night has virtually reigned in London for a period of sixty hours or so entailing not only grave ill effects to health but immense money losses, further handicapping an already too greatly handicapped industrial condition. Unfortunately in this country the inhabitants are not sufficiently alive to the advantages of a central heating system, but adhere for the most part to open domestic grates in which is consumed soft coal, with the result that innumerable chimneys are constantly belching forth thick, dirty smoke. According to Mr. David Brownlie, writing in the *Spectator,* December 13th last, black smoke can be completely wiped out of existence by technical methods that are now available and perfectly familiar to many chemists. After dealing with methods for eliminating black smoke from factory chimneys he proceeds to point out how the question of smoke from household fires may be settled satisfactorily. Roughly speaking fifty per cent. of the smoke of this country is due to household fires, which Mr. Brownlie avers could be reduced by fifty per cent. even when retaining the use of raw coal. The main solution of the black smoke problem is the low temperature carbonization of raw coal, so as to remove from it all the smokeforming elements, giving a residual smokeless and freeburning fuel.

DRUGS AND RHYTHM

Professor W. E. Dixon, professor of pharmacology in the University of Cambridge, speaking at a meeting of the Royal Society of Tropical Medicine held in Chandos Street Cavendish Square on December 11th, on scientific aspects of drug taking, said: "When I took Indian hemp experimentally, the rise and fall of the wave sensations were most delightful. Half the pleasure of smoking is due to the rhythm. One professor in Cambridge can only think properly by touching all the gateposts that he passes, and if he misses one, he has to go back to touch it to maintain the rhythm.

CANCER OF THYROID

At a meeting of the Section of Surgery of the Royal Society of Medicine held in London on December 3rd, under the presidency of Mr. Herbert J. Paterson, a discussion on the diagnosis of malignant disease of the thyroid gland was opened by Mr. James Berry. In the course of his remarks Mr. Berry pointed out that the commonest degenerations or ordinary goitres were fibrosis and calcification. The statement had recently been made in America that adenomata of the thyroid having a fibrous star shaped centre were apt to become malignant, but Mr. Berry definitely dissented from that view. In his own series of 373 cases from which he had removed solid, not cystic, adenomata only three or four eventually became malignant. The presence of a recently noticed hard lump in the thyroid region in middle age or later should always arouse the suspicion of malignancy, even in the absence of other sign, though most such hard tumors were not malignant. Careful palpation helped greatly in the differentiation. Hemorrhage was very common in thyroid tumors, but this was no indication of malignancy; indeed, among many cases of cystic adenoma and others in which bleeding occurred he had never seen any considerable spontaneous hemorrhage within a malignant thyroid tumor. It was seldom that patients with innocent goitre complained of difficulties in swallowing; even when the pharynx and esophagus were displaced it rarely was a permanent occurrence. But in malignant disease of this part, when the disease began at the back, dysphagia was often an early and important sign. Error was here also possible. However, Mr. Berry said that one of his main objects in bringing forward the subject was to draw attention again to the class of innocent thyroid swelling, which was mistaken frequently for malignant tumor. In the present day, when operations for thyroid disease were becoming increasingly easy and safe, there was a danger lest severe operations

hould be needlessly undertaken. He stated very efinitely that removal of the whole thyroid gland hould never be carried out, even for carcinoma of t. He had never done so himself, nor felt that he ught to have done it. He laid special emphasis on he fact that in the innocent variety of tumor there as nearly always present in the patient a waxy allor, which indicated commencing atrophy. It was he beginning of what was seen more markedly in dvanced myxedema. This waxy pallor was prac- ically always absent from the patient who had true alignant disease at that early stage before the rowth had penetrated the capsule. He had been any times impressed by the apparent general well eing of patients who were suffering from even ad- anced and extensive malignant disease.

PARIS LETTER

(*From our own correspondent.*)

PARIS, *January 10, 1925.*

CANCER RESEARCH

There is much talk of cancer here just now. In he first place there is the example set by heroic Professor Bergonié. It is the pride of France hat in spite of that ultra centralization bequeathed y Napoleon as a heavy legacy, there are in provin- ial cities more or less great physicians, surgeons, nen of science, who successfully fight the lure of the apital and who, sustaining life the while on emolu- nents miserably inadequate—generally with a fam- ly to support—hold up the torch of knowledge, ather around them veritable disciples animated by he same enthusiasm, and in the quietude of their entury old laboratories achieve epoch marking dis- coveries. As a rule they remain unknown to the nultitude, for they do not seek publicity, and when erchance a Nobel Prize falls their way the inquir- ng reporter sets forth to interview them with a hrug of the shoulders, as if to say: "Who the levil's he? Never heard of him before."

COMPLETE SACRIFICE

Such a one was Professor Bergonié, martyr to ex- erimentation with x rays and radium. Fingers, hen an arm were amputated; cancer developed but lacidly he continued his investigations, studying the ction of the atomic bombardment upon living cells n order that human lives might be saved. He was hirty-eight years old when Röntgen made his dis- overy in 1895, and from that time he consecrated is life to the study of the therapeutics of the x rays nd subsequently of radium. When cancer devel- ped he followed minutely the progress of the dis- ase. When he knew that he was doomed, he gave is small fortune for the creation of an institute for ancer research; before his death he gave his very ody to science, and the autopsy merely confirmed he clinical testament that he had left. Undeterred, ther modest savants are following in his footsteps nd Dr. Demenitroux died a few days later after levoting his life to the commercial production of horium. And Dr. Demenitroux, in his turn, has een followed to the grave by M. Marcel Dela- nande, his associate and collaborator. He was only hirty-four years old and was a former pupil of Madame Curie.

A GENERAL INQUIRY

Professor Bergonié has not died in vain, for his end has struck public opinion in forceful manner, fitly preparing the ground for a campaign for nation-wide action against cancer. France is realizing that while her population is decreasing steadily, cancer, equally steadily, is claiming more and more lives each year. So much so that the admirable organization known as the Franco-Anglo-American League against Cancer cannot collect funds fast enough to relieve the stricken, despite the untiring activity of the devoted band of men and women at its head. Of these, Mme. Henri Hartmann, née Lucy Deharme, an American who married the well known French savant, has just received from the Minister of Health the Cross of Knight of the Legion of Honor for her work as president of the Aid Section of the League.

AT THE ACADEMY

Public concern in connection with cancer is such that the echo thereof has reached the Academy of Medicine, which grave and reverend body, it must be confessed, it not invariably up to the minute. At its last sitting, the Academy received with favor a communication from M. Charton, of Besançon, concerning the prophylaxy of cancer. M. Charton outlines the results of cancer research to the present day and comes to the conclusion that there is room for much coordination. Undoubtedly this is so. Undoubtedly, also, the general practitioner could furnish interesting data if there were a centralizing organization ready to welcome his reports and figures. M. Charton asks the Academy of Medicine to become this centralizing body as he considers that, alone in France, it is in a position to appeal to the entire country for help. Perhaps, eventually, such a nationwide inquiry might help to solve the controversial questions of heredity and contagion. Moreover, the inquiry would certainly tend to discredit utterly the everincreasing number of quacks. It is to be hoped that the Academy of Medicine will give a favorable answer to the proposal.

POINTS OF QUESTIONNAIRE

Before taking any action the Academy will await the report of its commission on cancer, to which the matter has been referred. The idea is to reach every practising physician in the country and to avoid a cumbersome questionnaire, in order to facilitate the tabulation of the replies. It is felt that three questions should be sufficient, to wit:

1. What is your personal opinion, as based on observations in the course of your practice, on the transmission of cancer by heredity; give details of typical examples of socalled cancer families;

2. What is your personal opinion, also based on practical observations, on the transmission of cancer by contagion; if possible, cite typical cases;

3. Will you undertake, in the course of the next six months, to study any cases of cancer among your patients from the double point of view of heredity and contagion?

SUGGESTION FROM RUSSIA

In the meanwhile interest is manifested here in reports from Russia—published in the first instance in *Pravda,* the official Soviet newspaper—that Dr.

Molotkov has read a paper before the All Russian Congress of Ear, Nose and Throat Specialists relative to his method of treating concerous growths by cutting the nerves round the spot affected. Professor Grekov declared that experiments carried out at his clinic have so far confirmed Dr. Molotkov's theory. Several French research workers are particularly interested in this news because of past experiments on the same lines made in this country.

PROFESSOR FAURE

Nearer home, Professor J. L. Faure, one of the leading surgeons of the younger school in France, who has just been elected to the Academy of Medicine, has published an exhaustive work on uterine cancer (*Cancer de l'Utérus,* Gaston Doin, 8, Place de l'Odéon, Paris). In his 230 pages, accompanied by more than one hundred figures, Professor Faure deals with every phase of a question which was so controversial not so many years ago. He lays particular stress on the fact that "Cancer of the uterus presents absolutely different conditions according to whether it attacks the collar or the cavity." Professor Faure, naturally perhaps, favors surgical intervention, but he is careful to indicate that the dominating question is that of treatment, as present in the stage of complete evolution, with the consequence that no one can say whether that which seems true today will remain true tomorrow. As to results, from 1896 to 1906 the professor hesitated to operate for cancer of the uterus; nevertheless the results obtained induced him to persevere. He is a partisan of abdominal hysterectomy as against vaginal, and in this connection he gives full credit to Ries (Chicago) and Clark (Philadelphia). During the last three years Professor Faure has perfected his technic by the addition of Mickulicz drain and he has succeeded in reducing mortality from eleven per cent. to three per cent.

VIVISECTION AGAIN

The French public—as Macaulay might have said—in one of its periodical fits of morality, has again manifested concern regarding vivisection. The sensational press has been devoting space to horrible tales told by persons—anonymous for the most part—who assert that the neighborhood of institutions devoted to research resound with the pitiful shrieks and howls of the victims. It is the vivisection of dogs more particularly that stirs the readers of these newspapers. At as result the Minister of Health considered it necessary to send to the Academy of Medicine a letter proposing the limitation of experiments on live animals and also State supervision of laboratories where vivisection is practised, in order that such supervision might prevent "acts of useless cruelty."

PUBLIC REASSURED

Professor Charles Richet, whose versatility continues to be marvellous, for he figures in most controversies, from evoking spirits to remedies for tuberculosis, immediately jumped into the breach and asserted with characteristic impetuosity that, after the horrors of war, vivisection painted at its worst is a mild affair, and also that everything is justifiable if the result be the saving of human lives. The majority of Professor Richet's *confrères* are not so impulsive. They requested Dr. Balthazard to draft a reply to the Minister. Dr. Balthazard has had long experience of French laboratories. Naturally, he points out in the first place that no man of science would commit "acts of useless cruelty." Furthermore, those engaged in research have not waited for a public outcry in order to reduce to a minimum the number of such experiments. Finally the cinematograph has come, in its latest improvements, to restrict vivisection still further. Consequently the French world of science repudiates the allegations levelled against it.

LATIN AMERICA LETTER

(*From our own correspondent*)

Canal Zone, *January 6, 1925.*

STANDARDIZED QUARANTINE REGULATIONS

At the plenary session of the Pan-American Sanitary Conference held at Havana, Cuba, November 5 to 12, 1924, a sanitary code was designed to standardize quarantine procedure throughout the world. The code was signed and will be presented to the representatives of the eighteen nations for its ratification at the conference. Many matters of international sanitary importance were discussed at this conference. Assistant Surgeon General John D. Long, U. S. P. H. S., was present as representative of the United States. Dr. Carlos Enrique Paz Soldan of Peru was elected president for the coming year. Lima, Peru, has been selected for next year's meeting.

FOURTH PAN-AMERICAN CONGRESS OF CHILD WELFARE

Surgeon C. P. Knight, chief quarantine officer of the Panama Canal, has recently returned from South America where he went as a delegate to the Fourth Pan-American Congress of Child Welfare held at Santiago, Chile, November 12 to 19, 1924. The other delegates representing the United States were Professor S. M. Lindsay, of Columbia University, Miss Katherine Lenroot, assistant chief of the Children's Bureau, Miss M. McHugh, assistant director of the National Catholic Welfare Council of Chicago, and Mrs. M. C. Migel, of New York.

The congress was attended by representatives from nearly all the countries of Central and South America and the West Indies. By special invitation, Dr. René Sand of Belgium was present as an observer. He is well known on account of his affiliation with Red Cross work. The congress was divided into three sections, medicine, sociology and hygiene, the sessions being held mornings and afternoons. Many excellent papers were read and all showed that great progress is being made in these countries in the field of child health conservation.

During the conference the delegates were extensively entertained by civic societies of Santiago, which included daily sightseeing trips, various luncheons and banquets. After the congress most of the delegates proceeded to Buenos Aires, Argentina, to attend the Congress of Sociology which was held in that city the latter part of October. Professor Lindsay will then return to Lima, Peru, to attend the International Scientific Congress in December.

Of special interest to the delegates was the visit to the milk stations that have been established in the

city of Santiago and other cities in Chile. The National Society for the Protection of Infancy has established in Santiago eleven milk stations locally known as Gotas de Leche. At these stations milk is pasteurized and then distributed free to indigent cases. They are similar to some of our health centres in the United States.

NEW QUARANTINE REGULATIONS OF JAMAICA

The Quarantine Board of Kingston, Jamaica, has just issued new quarantine regulations with special reference to plague, yellow fever, smallpox and influenza.

The board considers the following countries as plague infected: Ecuador, Chile, Peru, Argentine, Brazil, Uruguay, Paraguay, Cape Verde Islands, Hong Kong, Azores, Ceylon, China, Java, Greece, Hawaii, India, Indo-China, Japan, Dakar, Straits Settlements, Chios Islands, Zanzibar, British East Africa, Madagascar, Mauritius, Rhodesia, Siam, Syria, Constantinople, Algeria, Jaffa, Haifa, Lisbon, Portuguese West Africa, Barcelona, Cartagena (Spain), Valencia, Malaga, Mesopotamia, Bolivia, Canary Islands, Tunis, Morocco, Uganda, Celebes Islands, Russia (certain provinces), Siberia, Union of South Africa and West Africa.

The board considers the following countries infected with yellow fever: Bahia and Pernambuco, Brazil; San Salvador; Spanish Honduras (Pacific Coast); and West Africa (French Dahomey).

The regulations compel passengers from Colon, Panama, Cartagena, Puerto Colombia, Santa Marta, and from the Republic of Mexico, who desire to land at Kingston, to show marks of recent successful vaccination, or to submit to vaccination on voyage, or be vaccinated at the detention station and remain there until evidences of a take are present, or to remain there fourteen days.

Passengers from Costa Rica, Guatemala, Cuba, Haiti, Santo Domingo, Spanish Honduras and Nicaragua must be vaccinated on arrival or show evidences of recent take.

The board considers influenza a quarantinable disease and passengers are required to be two and a half days at sea before arrival and the ship surgeon must certify that there is no illness on board at the time of arrival.

LIQUOR FILLED TRUNKS SEIZED BY ZONE POLICE

As is customary with the Canal Zone Government, the enforcement of prohibition is directly in the hands of the Governor, and this power is delegated to the Police Department of the Canal.

While an army transport was lying at the Balboa pier waiting to proceed to San Francisco, two heavily laden trunks arrived at the dock consigned to a person whose name was not on the list of passengers. Before the arrival of the trunks, the police officer on duty at the dock had been tipped off by telephone that trunks filled with booze were leaving Panama City for the docks. The driver of the truck was arrested but later relased as he was an innocent party to the transaction. The trunks were taken to the police station and then opened, when it was estimated that there were six hundred dollars worth of different kinds of spirits. The contents will be dumped into the Bay of Panama

CANAL ZONE SANITATION

The Report of the Canal Zone Health Department for the year 1923 has some very interesting data regarding the work of protecting the Canal from disease. While the quarantine division is chiefly concerned with preventing the introduction of disease from foreign shores, the division of sanitation does the work within the Zone and in the terminal cities of Colon and Panama. The Division of sanitation is interested in preventing a possibility of spread of plague by eliminating the rat and in preventing yellow fever and eliminating malaria by its unusually good mosquito control. In his report to Colonel Chamberlain, the chief health officer, Dr. Dalferes P. Curry, in charge of the division of sanitation, makes the following remarks: "As a result of the painstaking work by the sanitary forces and by splendid cooperative efforts of other divisions of the Panama Canal, the terminal cities are approaching a condition which would render the spread of plague most unlikely even if a human case or an infected rat were introduced from some vessel. No case of human plague and no infected rat have been known to exist since 1905, in which year two colored laborers contracted the disease at La Boca and died. Many thousands of rats are caught each year and examined at the laboratory, but no case of infection has been found in many years.

Malaria among the employees for the year was 19 in 1000. The average rate during the first ten years of construction was 393 in 1000 and during the last ten years was 28 in 1000. The rate of 19 in 1000 for the year just ending is an indication of the continued efficiency of the Health Department in this direction. Assistant Surgeon General Henry R. Carter, United States Public Health Service, who took such an important part in the sanitary campaign during construction days, recently visited the Zone and expressed himself as astonished and delighted at the results now obtained by the Division of Sanitation. Along with efficiency has come economy. The sanitary forces are gradually being reduced, a step made possible by the change from temporary to permanent measures of control. There is no foundation for the occasionally heard statement that sanitation is being neglected or that the physical welfare of the Zone inhabitants is less regarded than formerly.

HUMAN PLAGUE IN PERU

Under date of November 11th, Peru reports human plague as follows: In Lima, thirteen cases, ten deaths; in Callao, one case; in Huancabamba, six cases; Chancay, one case; Miraflores, one case.

GENERAL PERSHING VISITS THE CANAL ZONE

The delegation headed by General John R. Pershing, including Admiral Dayton and ex-Congressman Hicks of New York, arrived on the battleship *Utah* en route to the Ayacucho Centenary that will be held in Peru in December commemorating the decisive battle which gave Peru its independence from Spanish dominion. During his stay here General Pershing and party were entertained by officials of the Army and Navy, the President of Panama, the Governor of the Panama Canal and the American Chargé d'Affaires.

Book Reviews

LISTER

Lord Lister. By Sir Rickman John Godlee, Bt., K.C.V.O., M.S., F.R.C.S. Third Edition, Revised. Oxford: Clarendon Press; New York: Oxford University Press, 1924. Pp. 686.

Little need be said of this most attractive work on the life and work of Lord Lister. Works such as this one should form the background of every medical library. The life, trials and accomplishments of Lister form one of the most fascinating chapters in the history of medicine if not in science. Godlee has approached his task with reverence which has not been marred by a lack of clarity and human understanding. The present, third edition of his work contains a résumé of the present day treatment of wounds, including the methods perfected during the war.

DISEASES OF THE EYE

Affections de l'oeil en médecine génêrale diagnostic en traitement. Par F. Terrien, Professeur Agrégé à la Faculté de Médecine, et G. Cousin, Chef de Laboratoire d'Opthalmologie à la Faculté de Médecine. Paris: Masson et Cie., 1924. Pp. viii—510.

The work is divided into three large parts. The first treats in a general way of examination of the eye and of its functional disorders, the second is devoted to the elucidation of symptoms as they occur in diseases of the eye and its neighboring organs, and the third, the largest and most important part, takes up ocular conditions in their relation to general diseases. The work is distinctly clinical in character, and aims chiefly to aid the general practitioner in recognizing and treating eye conditions as met with in general practice. A rather interesting, though all too short, chapter is devoted to the eye in old age, while syphilis and tuberculosis of the eye are treated at commendable length. The authors have succeeded in grouping together in a systematic and concise manner all that is known up to date of the interrelations between the internal secretions and the eye, and this chapter on endocrinology as well as the one on neuro-ophthalmology deserve special mention. Taken as a whole this can be recommended as a dependable reference book for both the specialist and the general practitioner.

X RAY THERAPY

The Principles and Practice of Röntgen Therapy. By I. Seth Hirsch, M.D., Director, X Ray Department, Bellevue and Allied Hospitals, New York. With Formulæ and Dosage Table, by Guido Holzknecht, M.D., Professor of Röntgenology, University of Vienna. Three Hundred Illustrations and Fifty-seven Tables. New York: American X Ray Publishing Company. 1925.

This excellent work by an eminent New York radiologist is a comprehensive attempt to formulate the principles upon which modern röntgen therapy is based, and to standardize the technic of the application of the radiation as a therapeutic agent. The use of the x ray for this purpose, as the author points out, involves physical, biological and chemical problems which must be understood if the radiation is to be applied in a rational manner. The author has summarized the enormous mass of literature written on this subject, with a critical eye and with severe judgment.

From the great volume of experimental research and theory he has selected what appeared to be most fundamental and important and has arranged his data in logical order and sequence. Throughout the book the author stresses the necessity of avoiding overdosage with its consequent depression of the general vitality of the organism. He objects to the massive dosage method of the Germans and furnishes proof for his contention that the vital resistance is so greatly depressed by such methods that the treatment defeats its own purpose.

Incorporated in the body of the work is a section of the dosage system of Holzknecht, a system which correlates practical and clinical experience in x ray therapy and puts it in tabular form, giving formulæ for treatment in various diseased conditions. The author has divided his work into three main divisions, the generation, measurement and application of x rays; under the last heading he goes thoroughly into the theoretical, practical and clinical aspects of x ray dosage.

The author and publishers have combined to produce a most excellent work, which not alone covers the ground thoroughly, but presents the subject in an attractive and interesting form. In addition, there is presented a vast amount of valuable information on the subject of cancer, which furnishes the most active field for röntgen therapy.

Altogether the volume is one of unusual quality and can be commended to medical practitioners and research workers in this field.

PRESCRIPTION WRITING

Essentials of Prescription Writing. By Cary Eggleston, M.D.. Third edition, revised. Philadelphia and London: W. B. Saunders Company, 1924. Pp. 146.

This small book is very carefully prepared, as usual, and full of information on the subject that it treats. Owing to the fact that Latin is not now required as necessary for entrance into many medical schools, the author has been compelled to give considerable primary instruction in Latin, if prescriptions must still be written in Latin. The reviewer thinks that if medical schools do not require Latin as an entrance requisite, it is hardly necessary for the professor of pharmacology or therapeutics to teach Latin, as it is a hopeless task to cause the medical student to write correct Latin prescriptions without more knowledge of that language. The author's list, on page thirty-two, of "verbs in common use in prescriptions" is not quite a statement of fact. Very few of the verbs he lists are in common use, in fact, they practically never appear on prescriptions of physicians of the present day.

The reviewer regrets that the author of this instructive book did not see fit to make the metric system more popular. His prescriptions still represent three and four ounce mixtures instead of fifty or one hundred cubic centimetre mixtures, and if he admits, as by foot note on page sixty-three, that five c. c. represents more exactly the ordinary teaspoonful, it is hardly correct to have prescriptions com-

puted on the mistaken idea that a teaspoonful represents only four c. c., or one fluidram. If five c. c. represents a teaspoonful, as is most generally the fact, twenty doses would equal one hundred c. c., and the computation of doses in the metric system becomes very simple.

On page seventy-five is illustrated a five per cent. solution of phenol, and the amount ordered is four ounces. This rather seems like *reductio ad absurdum.* Why not order phenol 5, water up to 100 c. c.?

As to practical prescription writing, the modern clinician would never spend time to write such instructions as this: *Misce et fac emulsum secundum artem.*

CLINICAL MEDICINE

Einführung in die klinische Medizin. Eine kurze Darstellung ihrer Grundbegriffe für Studierende. Von Walter Marle, Generaloberarzt a.D., Berlin. Mit 379 Abbildungen im Text. 1. Band. Urban & Schwarzenberg, 1924.

This *Introduction to Clinical Medicine* is intended to supply the medical student, who is beginning the study of the clinical aspect of medicine, with the necessary knowledge and it is recommended for preliminary study. The illustrations are well selected from various authors. A bibliography is appended to each chapter. The material presented is necessarily limited to fundamental facts which are necessary for the comprehension of clinical methods of examination and study. The first portion of the book deals with general pathology; the second part takes up clinical microbiology and the theory of immunity; the third portion deals with general methods of examination and diagnosis and the fourth portion is concerned with general therapy including all its various branches and types of treatment. While much is necessarily omitted that is found in the larger textbooks, this book contains much that is valuable for the medical student and also much that can be found in no other books. It is admirably adapted to the purpose for which it was written.

EAR, NOSE, AND THROAT DISEASES

A Manual of Diseases of the Nose, Throat and Ear. By E. B. Gleason, M.D., LL.D., Professor of Otology, Medico-Chirurgical College Graduate School, University of Pennsylvania. Fifth edition, thoroughly revised. Philadelphia and London: W. B. Saunders Company, 1924. Pp. 660.

The value of this very serviceable, and in some respects excellent manual, is considerably impaired by the retention from former editions of some out of date and antiquated matter which may possess some historical interest for the specialist, but is surely out of place in a work primarily designated for students and general practitioners whom it is intended to supply with the essential facts of rhinology, laryngology and otology, in as concise a form as possible. It is questionable whether such topics as tonsillotomy (but rarely performed nowadays by any progressive laryngologist), galvanocautery and caustic treatment of anterior hypertrophies of the turbinates, anterior inferior turbinectomy, or the employment of paraffin in any kind of nasal work, can claim a rightful place in a modern textbook of laryngology. We also doubt whether an adenoidectomy can properly be performed without anesthesia, in fairness both to the patient and the operator, except in very young infants. We wish we could bring ourselves to agree with the author's evident preference for doing tonsillectomy in adults under general anesthesia as against local. While the subject is still *sub judice,* as it were, there is an unmistakable trend of recent years toward employing local anesthesia in all such cases, especially in view of the preponderating number of lung abscesses following general anesthesia.

However, with these exceptions, we can heartily recommend this treatise both to the general practitioner and to the specialist as a useful textbook containing in a condensed form most of the salient points on diseases of the ear, nose, and throat. Deserving of special praise is the treatment of the sinuses, which is thoroughgoing and quite exhaustive, and the hearing tests, the mastoid operations and the functional testing of the labyrinth. A valuable appendix to the book is a list of formulas elucidated by the author's interpolations, occupying some forty pages, and containing a rich and varied assortment of prescriptions for sprays, washes and the like, of considerable value to the practising laryngologist.

PSYCHIATRY

Manual of Psychiatry. For the Medical Student and General Practitioner. By Paul E. Bowers, M.S., M.D., Philadelphia and London: W. B. Saunders Company, 1924. Pp. 365.

This book has many commendable features. The subject is clearly handled. The material is presented in a straightforward, simple way. This makes the book readable and an accessible reference book. The material is handled from the present day, we might say most modern viewpoint. The general practitioner or medical student could not do better for a first book on psychopathology.

PSYCHIATRY

Aids to Psychiatry. W. S. Dawson, M.A., M.D., Oxon., M.R.C.P., Lond., D.P.M. New York: William Wood and Company, 1924. Pp. 477.

A brief outline of the various more common psychopathological affections which contains the diagnosis, differential diagnosis, treatment and prognosis of the conditions covered. A useful guide for nurses and general practitioners who encounter these cases from time to time. In formulating his concepts there is a compromise between the descriptive psychiatry of Kreaplin and some of the more modern functional concepts. Somewhat too little recognition is given to the dynamics of the unconscious.

MOTHER AND CHILD

The Canadian Mothers' Book. By Helen MacMurchy, M.D., chief of the Division of Child Welfare of the Dominion Department of Health. Illustrations. Ottawa: Department of Health, 1923. Pp. 135.

This little book has a subtitle telling the reader that it is *The Little Blue Book, Mother Series Number 1,* and its attractive blue cover confirms the statement. Dr. MacMurchy, the author, is a well known writer on subjects related to infant and child health and welfare, and in this work she follows her usual method of presenting her subject in a cheerful, informal and sympathetic yet thoroughly practical and scientific manner. Excellent illustrations add to the book's attractiveness and enhance the value of the text.

LOVE

The Nature of Love. By Emanuel Berl. Authorized Translation by Fred Rothwell. New York: The Macmillan Company, 1924. Pp. xi, 278.

This book is written with a stimulating clearness which apparently has in no wise been marred in translation. It is aphoristic in the richness of its statements as the author pursues the nature of love. He seeks in vain to find love's causality in any of the accepted conceptions of its origin. Its nature cannot be learned thus. Nor do its biological significances nor its social manifestations bring it to a definition. Psychology may hunt down its pluralities, finding some single simpler manifestation behind a long train of repetitions, as psychoanalysis has done. This does not entirely satisfy the author, nor can there be, he believes, an attempt on the part of such psychology to identify these dynamisms without a resort to metaphysics.

The author himself finds amid the varieties of love's manifestations, its seeming deceptions, its apparent instability, three distinctive elements, which he confesses himself unable to reduce further. Love is a thing dynamic, a will, *"the love of life for life,"* and as such, subjective. Then it is something pertaining to the object, the intuition of that object, which has no goal beyond. Finally, it is a fusion of these two aspects, which synthesizes this intuition with the subjective desire. Thus is love not defined but more clearly understood in its functional activity. Very suggestive, too, is the author's discussion of hate as the negative of this love of life; the hatred of life, which would destroy it; or, perhaps, that which withdraws into a passive rejection of it. Berl reaches for a mystic something beyond the separate revelations of psychology, but the presentation of his thought clarifies our psychological thinking without losing us in mystifying clouds.

SYMBOLISM OF THE CANE

The Gold Headed Cane. By William Macmichael, M.D., with an Introduction by Sir William Osler, Bart., M.D., F.R.S., and a preface by Francis R. Packard, M.D. New York: Paul B. Hoeber, Inc., 1925. Pp. 260. Illustrated.

As is well known to the student of medical history, the cane, and particularly the cane with a head of gold, silver or ivory, has a definite symbolic significance. In olden times, it was considered to be an essential part of the equipment of every physician, and was associated with the wig and ring, all of which stood for deep learning, wisdom and power. Other forms of the cane, with a similar symbolic meaning, were probably the herald's staff, the wands of primitive peoples and of fairy tales, the caduceus of Hermes, the wand of Aesculapius, the staves of sheriffs and constables, and the surgeon's club. The making of a good appearance was probably the strongest motive that led to the carrying of a gold headed cane by physicians, but it has been suggested that others may have entered in, as for instance the old beliefs that gold was lifegiving and had medicinal properties, and that fustigation was a sovereign remedy, and also perhaps the need of a weapon for selfdefense. The head of the cane was usually hollow and perforated so that it could hold aromatic preparations to be inhaled as preventives against contagion. This particular cane had instead of a knob a cross bar for a top, probably, Munk has suggested, because Dr. Radcliffe, its first owner, was "a rule unto himself," and wanted a cane different from those of other physicians.

Such a gold headed cane tells its own story through the pages of Dr. Macmichael's book, from 1869, when it acquired a head and so became "conscious of existence and capable of observation," until 1825, when it was deposited in a corner closet of the library of the New College of Physicians, London. The reader is pleased to learn through Dr. Packard's preface, however, that the cane was not condemned to eternal oblivion, but now occupies a glass case in the library of the college, where visitors may gaze and admire. Dr. Munk in a third edition published in 1884 wrote a continuation of the story in imitation of Macmichael's style, bringing the narrative down to 1871.

The cane was carried successively by Radcliffe, Mead, Askew, Pitcairn and Baillie, and its head bears engravings of their various arms. Reproductions of these form the vignettes of the five chapters into which the volume is divided. Under the presidency of Sir Henry Halford, 1820 until 1844, the College of Physicians underwent a great awakening, including the acquirement of a beautiful new home and the inauguration of the famous evening meetings. Dr. Packard writes that doubtless a great part of Sir Henry Halford's success was due to the seconding of his efforts by Macmichael. "In nothing could he have succeeded better in awakening renewed interest in the venerable college than by directing attention to its past history and to the achievements of the illustrious men who had been connected with it. It was probably this desire which led Macmichael to utilize his erudite knowledge of the subject in the compilation of the fascinating book to which he gave the name of 'The Gold Headed Cane.'"

Dr. John Radcliffe, the first owner of the cane, gave to Oxford the Radcliffe Infirmary and the Radcliffe Camera or Library, originally designed to be the scientific part of the Bodleian Library, and was the founder of the Travelling Fellowships. The account of Richard Mead, the second owner, is perhaps the best in the book. He was a complete contrast to his predecessor—a scholar where Radcliffe was ignorant of books; courtly and polished where Radcliffe was rude and overbearing. Dr. Johnson once said of Mead that he lived more in the broad sunshine of life than any man he knew. With the name of the next possessor of the cane, Anthony Askew, we associate the famous Bibliotheca Askeviana, priceless treasures lost to science through an auction sale. Pitcairn's story is rather vaguely told and we learn comparatively little about him. Baillie, the last carrier of the cane, was the nephew of John and William Hunter and to him more than to any other man is due the close combination of pathology with clinical medicine.

Macmichael's style is delightful in its quaintness, humorous quality, and intimacy of narrative. The present edition follows the text and illustrations of the second edition, which was revised, augmented and published by the author himself. The technical makeup of the book follows, in the usual style of the publisher, the highest standards of the printing and publishing arts.

Medicoliterary Notes.

According to the London *Daily Telegraph,* the English production of *What Price Glory?* has aroused almost as much excitement among naval and military authorities as it did in this country. The reviewer says: "As a picture of war, the play is ridiculous, to British eyes at any rate, and to many Americans as well. Accustomed as we are to stretching our imaginations in the theatre, we cannot believe that a man like Flagg could remain in command of a company for a single day. Our own staff colonels are not in the habit of allowing a mere captain to tell them what he thinks of the Army in general and the staff in particular, in terms more forceful than polite, as Flagg does. Nor should we expect to see our officers and N. C. O.'s getting drunk together and grappling with each other on the floor of a French *estaminet.* Several Americans have assured me that things like these did happen in the American army; one of the authors of this play was in the Marines himself. But still I am loath to believe it. Any way it is a matter of no great importance, for this is a play of character, not of incident. The events may be false or exaggerated, but the people are alive. Every sentence, every joke, every swear word even, rings true. . . . War and the training for war make men like Flagg and Quirk. . . . A play like *What Price Glory?* is a wholesome reminder that there was another side to the medal."

* * *

Eye Hazards in Industrial Occupations is the title of a recent publication by the National Committee for Prevention of Blindness, prepared for the use of safety engineers and inspectors, industrial physicians and nurses, and for government, trade association and social agency officers.

* * *

Chinese scholars reason thus: For centuries China lived the life and cherished the ideals that Europe is living and serving today. She has passed through that experience and now she has retired to a life of leisure. She has learned that the really important task of living is not to contrive new inventions and machinery, or even to subdue the forces of nature, but to develop the human faculties, and these change very slowly. Those foreign nations that survive as long as China has survived will eventually understand our attitude. The others will die, as many nations whose existence China can recall have already died and completely vanished from the earth.—*Living Age, quoted from Revue Mondiale.*

* * *

Swedish hospitals for the insane are now almost universally using moving picture films selected by psychiatrists as a form of treatment through diversion. Sanitariums for the tuberculous are doing the same for the relief of the states of mental depression so usual among convalescent patients. Films are used also for auxiliary training of the tuberculous and of the deal and dumb.

* * *

The *London Mercury* for October contains a very amusing story entitled The Man Who Stole the Pelican, by I. A. Williams.

* * *

In Japan a Japanese eugenics association has recently been organized and will publish a monthly bulletin for the education of the public in the subject.

* * *

The monthly number of the *Living Age* for November publishes three representative European comments on the Leopold-Loeb trial, the first from the conservative London *Saturday Review,* the second from the *New Statesman,* organ of the intellectual wing of the Labor Party, and the third a translation from the Viennese Socialist daily, Arbeiter Zeitung.

* * *

The Oxford Press has just issued a paper bound pamphlet on *The Debt of Science to Medicine,* by Archibald E. Garrod, who delivered the contents as the Harveian Oration before the Royal college of Physicians of London.

* * *

A recent issue of the *Japan Times and Mail* comments on the present day demand in that country for snakes for medicinal purposes, which is so large that the consumption for the country as a whole has been estimated as between four and five millions, and for Tokio alone as between five and six thousand. About eighty per cent. of these are roasted and powdered or dried and made into pills and capsules. The rest are for table use, boiled, baked or roasted. In some regions the wild snakes are becoming so scarce that snake farms for breeding purposes are being contemplated.

* * *

The Zoological Gardens of London have recently been making an exhaustive study of the influence of weather conditions upon men and animals. Among two of the important conclusions arrived at are that cold is not necessarily injurious if it is dry cold; and that damp is not necessarily harmful unless accompanied by cold. Recommendations for humans are given, drawn from the study in relation to animals.

* * *

Westminster Abbey is being cleaned, renovated and in places restored. Incidentally many forgotten beauties, artistic, architectural and otherwise, are being brought to light, notably in the chapel of Henry V, and in the Erasmus chapel.

* * *

Donald B. McMillan, recently returned from the Artic, should be able to contribute an interesting new page to folk psychology as a result of his sojourn among the Eskimo. "The Eskimo," he reports, "have a very clear and unquestioning belief in an immortal soul. They reverse our ideas of the prospective dwelling places of the righteous and the wicked. Their hell is in the heavens—it seems quite natural when you see an Artic blizzard bearing down upon you—and their heaven is in the warm, sheltering earth."

* * *

Canned whale meat, it is reported, has become an established commodity along the West Coast of Africa, where the entire stock of whale meat caught off British Columbia during last year was sold.

* * *

Tokyo's most famous theater, the Imperial, according to the *Living Age,* is one of the first buildings in the city to arise from last September's disastrous earthquake. It has a revolving stage, a device long used in Japanese theaters, and its decorations and furnishings are planned to give effects of quiet and restfulness, instead of the former gilt splendor in the worst Western taste. Chinese and Japanese theatrical companies will occupy the boards for the greater part of the winter, and there are to be also recitals by the violinist Zimbalist and by Mary Garden.

* * *

Bernard Shaw's play, *Mrs. Warren's Profession,* banned for more than thirty years by British censorship of the stage, is at last to be produced in London. It has appeared in this country, and in France, Germany and Russia, but not in England. Mr. Shaw's comment (*Living Age*) was: "The news is only too true. Now that I have reached the venerable age of sixty-eight in the odor of sanctity, the Lord Chamberlain lets loose on me a terrible play written thirty years ago, when I was a younger tiger fearing neither God nor man—a play which I was depending on him to keep locked up so that I might end my days in peace. . . ."

* * *

America's Interest in World Peace is the title of a pamphlet by Dr. Irving Fisher, of Yale, published by Funk & Wagnalls. It is a plea for America's entrance into the Permanent Court of International Justice at the Hague and into the League of Nations.

* * *

One of the interesting features of the International Health Conference held last May at Wembley, England, was the exhibit and story of the Framingham Health Demonstration, conducted by the National Tuberculosis Association in cooperation with various health agencies in Massachusetts.

* * *

At a recent meeting of the Academy of Sciences in Paris, Dr. Louis Paul le Gendre read a paper in which he propounded a plan for the extermination of stinging mosquitoes by a nonstinging variety which he claims to have discovered in Brittany. He tried the experiment of transporting some of the harmless variety to another department and found that in a very short time they apparently did away with their stinging brothers and completely supplanted them.

Abstracts from Current Literature

ENDOCRINOLOGY

Cancer and Endemic Goitre.—Otto Stiner (*Schweizerische medizinische Wochenschrift*, July 3, 1924) found that in the regions of Switzerland showing few goitres carcinoma of the gastrointestinal tract was less frequent than in those showing the frequent occurrence of goitre. He does not attach any etiological significance to this fact, but he does attach importance to dental caries, as the cantons showing the frequent occurrence of dental caries also show a frequent occurrence of goitre and carcinoma of the digestive tract. This result may be due to the use of nutrition with deficient vitamines.

Treatment of Exophthalmic Goitre.—G. W. Holmes, J. H. Means, C. A. Porter, E. P. Richardson and M. P. Starr (*Boston Medical and Surgical Journal*, August 14, 1924) are of the opinion that iodinization followed by subtotal thyroidectomy while the metabolism is normal, is the best program for the treatment of exophthalmic goitre that has yet been advanced. X ray will still have it place in patients in whom, for any reason, operation is undesirable, or who refuse operation.

Individual Treatment of Goitre with Minimum Doses of Iodine.—Fritz Kaspar (*Wiener klinische Wochenschrift*, July 17, 1924) contained some excellent results in the treatment of parenchymatous goitres, especially in children, with extremely small amounts of potassium iodide. Such a dose has not only a prophylactic value but also has great therapeutic significance, especially in juvenile goitres. In the latter, a large portion of the goitres were made to disappear entirely or for the most part with the daily use of iodine (totaling 0.001 to 0.003 grams of potassium iodide a month) in one to two months, others required 0.001 to 0.004 grams within four to six weeks. About one third of the cases showed at first only little change with this form of treatment. Even parenchymatous goitres in adults and individual recurrent goitres to a great degree showed distinct involution—some within one to two months and others in five to ten months on a monthly dose of 0.001 to 0.006 grams of potassium iodide, but adenomata and colloid goitres remained unchanged. With this dose, with strict individual indication and control the total monthly dose of 0.008 gram of potassium iodide and even a little more may be given harmlessly and successfully.

Congenital Hypogonadism.—Mark S. Reuben and G. Randolph Manning (*Archives of Pediatrics*, July, 1924) report the following findings in congenital hypogonadism: The children are oversized and overweight for their age; the genitals are undeveloped; there are no signs of the presence of secondary sexual characteristics. The mentality is normal. The part below the umbilicus is larger in proportion to total strength than in normal children. The thymus is often persistent; the pituitary may be normal or slightly enlarged. These patients usually present contours of a feminine type associated with general adiposity. The roentgenograms of the wrists shows delayed ossification. The basal metabolism may be subnormal and the sugar tolerance may be normal.

Influence of Thyroidectomy, Gonadectomy, Suprarenalectomy, and Splenectomy on the Thymus Gland of Rabbits.—David Marine, O. T. Manley, and Emil J. Baumann (*Journal of Experimental Medicine*, October, 1924), report the data relative to the effect of these operations and combinations of these gland removals on the thymus gland as measured by its involution, persistence, or regeneration in rabbits. The data of 373 protocols are included in this study, and the following facts are brought out by this statistical analysis: Thyroidectomy hastens involution of the thymus and other lymphoid tissues. Gonadectomy delays thymus involution. Sublethal but sufficient injury of the suprarenal function with intact thyroid prevents thymus involution and causes regeneration even of the involuted thymus. It also causes hypertrophy of other lymphoid tissues. Thyroidectomy prevents thymus regeneration following suprarenalectomy, probably for the same reason that thyroidectomy hastens normal thymic involution. The combined effect of suprarenalectomy and gonadectomy results in certain lymphoid and thymus hyperplasia in rabbits which persists until regeneration of accessory interrenal tissue corrects the physiological defect. The syndrome thus experimentally produced resembles status lymphaticus and is believed to depend mainly on a partial loss of certain functions of the interrenal and sex glands rather than of the chromaffin tissue. The normal and abnormal lymphoid and thymic hyperplasias of infancy and childhood are thought to be manifestations of a functional underdevelopment of the interrenal and sex glands of varying intensity. The socalled lymphatic constitution which underlies or accompanies exophthalmic goiter, Addison's disease, and acromegaly also appears to be dependent on a partial suppression of certain functions of the interrenal and sex glands.

Are Guanidines Present in the Urines of Parathyroidectomized Dogs?—Isidor Greenwald (*Journal of Biological Chemistry*, March, 1924), states that the investigations reported seem to offer good reason for refusing to accept without further evidence, the idea that tetany is due to guanidine intoxication. There are only two well authenticated changes after parathyroidectomy. One is the lowered calcium content of the serum or plasma, and the other is the diminished excretion of phosphorus in the urine. These must be regarded as being intimately connected with the sequence of symptoms observed. No theory of the causation of tetany can be considered adequate if it fails to take both of these into consideration.

Influence of the Suprarenal Gland on the Thymus.—Henry L. Jaffe (*Journal of Experimental Medicine*, September, 1924), presents results based on a study of sixty-six double suprarenalectomized rats, and twenty-one nonoperated controls. Following this operation, there was a secondary hyperplasia of the thymus resulting in enlargement of the organ, the height of the curve of the enlargement being reached in from three to five weeks after the operation. The females show the enlargement more readily than the males, and it is not prevented by a previous pregnancy, occurring even when the animal has lost weight after operation. The explanation suggested for the enlargement of the thymus following double suprarenalectomy is a disturbance of the interrelations between the gonads, the thymus, and the interrenal gland (suprarenal cortex). A possible relationship between the enlargement of the thymus occurring in Addison's disease, Graves's disease, status thymicolymphaticus and that following double suprarenalectomy is suggested.

Treatment of the Endocrine Glands with the Ultraviolet Rays.—J. Saidman (*Bulletin de l'Académie de médecine*, July 22, 1924), reports good therapeutic results in seventeen cases from treatment of the ovaries with the ultraviolet rays. In two cases of the amenorrhea of puberty in girls fifteen and one half and sixteen years of age, menstruation set in after six to ten treatments with these rays. In four young women of eighteen to twenty-five years with scanty, irregular, usually delayed menstruation with pain, the menstruation returned to normal and the pain disappeared in three instances after eight to twelve treatments. Among eight cases of very irregular menstruation attending active tuberculosis of the lungs, peritoneum or joints, the function was made regular by four to fifteen exposures in seven instances. In three women with artificial menopause symptoms following x ray irradiation of the ovaries for fibroids or metrorrhagia, fourteen to twenty treatments partly or wholly relieved the hot flushes and dizzy spells, and in the one obese subject it reduced the body weight. In a young woman of twenty-one years who, since the age of fifteen, had had irregular menstruation, became obese and sensitive to cold, with dry skin and fatigue upon the least exertion, thirteen treatments in two months took off nine kilograms of weight, reduced the waistline by nine centimetres, regulated the menstruation and enabled the patient to work. The most effective dose appeared to be that producing a discrete actinic erythema. A two thousand candle power mercury vapor lamp was used as the source of the rays. At the first sitting the whole body was irradiated in three or four segments for one or two minutes each from a distance of fifty centimetres. At

subsequent treatments the distance was reduced by five centimetres to a minimum of thirty centimetres and the duration increased by one-half to one minute to a maximum of eight or ten minutes. When no erythema followed in six to twelve hours, supplementary local exposures over the hypogastrium, thyroid and lumbosacral region were made, causing a local erythema which assisted the general effect. Two or three treatments a week were given. There were no untoward results other than itching for one to three days.

Electrocardiogram in Cretinism and in Mongolian Idiocy.—Catherine Thacher (*American Journal of Diseases of Children,* July, 1924) states that in pure cretinism, as in myxedema, the T-wave in the electrocardiogram is lowered, flattened or even inverted, and can be brought up to normal by the administration of thyroid. In Mongolian idiocy there is no characteristic change in the electrocardiogram.

Brain Development in Anuran Larvæ after Thyroid or Pituitary Gland Removal.—Experiments conducted by B. M. Allen (*Endocrinology,* September, 1924), served to show that the brains of tadpoles deprived of either the thyroid or the pituitary gland remain undeveloped in proportion to the stage at which the gland was removed, corresponding in this respect to the development of the hind legs in especial and the body in general.

Hyperovarianism and Its Specific Treatment.—By injecting Möbius's serum from thyroidectomized animals A. do Amaral (*Endocrinology,* September 1924), succeeded in benefitting cases of hyperovarianism, causing complete cessation of menorrhagias of long standing by reestablishing hormonic equilibrium.

Differential Diagnosis of Incipient Tuberculosis and Incipient Goitre.—Both these conditions, R. Pettitt says (*Endocrinology,* May, 1924), are characterized in the incipient stage by lassitude, fatigue, weakness, nervousness, rapid pulse, loss of weight, cough, night sweats, and dyspnea In addition to these the goitre patient manifests palpitation, tremor, and heart changes, and has increased appetite, while tuberculous subjects fail in appetite. Until an accurate simple method for the determination of the basal metabolic rate can be perfected, it will be impossible for the ordinary practitioner to utilize this procedure as a diagnostic test.

Use of Seaweed in the Prevention and Treatment of Goitre.—J. W. Turrentine in *Endocrinology,* May, 1924, strongly advocates the administration of iodine in the form of kelp "processed" and made into tablets. Patients so treated have experienced an immediate restoration of the metabolic ratio to normal and prompt subsidence of tachycardia and tremor.

Phagocytosis in Toxic Goitre.—Professor N. Goormaghtigh (*Endocrinology,* May, 1924), has made a microscopical study of two goitrous thyroids, one removed after ligation of the arteries, the other without ligation. Beside the well known lymphoid infiltration of toxic and exophthalmic goitre, he observed a marked phagocytosis of thyroid cells. This was seen both with primary hypertrophy, so-called, and where degenerative colloid areas existed in addition to active lobes. Only those thyroid acini were found to undergo phagocytosis that were newly differentiated and gave evidence of great functional activity.

Tumors of the Adrenal Cortex in Relation to Pseudohermaphroditism.—Knud H. Krabbe reports a newborn male pseudohermaphrodite (*Revue Française d'Endocrinologie,* April, 1924), having labia majora and a clitoris. On one side he had a tiny testicle with islands of tissue resembling that of the adrenal cortex; on the other the testicle was replaced by a tumor of considerable size consisting of corticoadrenal tissues. Both adrenal glands presented marked aplasia. There was also spina bifida with paralysis of the lower limbs.

The author believes the pathogeny of these malformations probably lies in arrested development and disorganization in the lower segments of the organism, the aplasia of the external genital organs and the spina bifida being parallel results of that arrest. The sphere of the adrenal cortex and that of the sex glands are intimately connected in the early stage of fetal life. In the male embryos the sex glands are always purely testicular, while in female embryos they are bisexual, consisting of an external ovarian portion and an internal testicular portion. This latter relation is the explanation of the virilism of women and little girls with adrenal tumors. Krabbe states emphatically that there is no definite proof of the secretion of the adrenal cortex having any relation to the sex organs. All the anatomical alterations recorded may be explained by local relationships, that is to say, the fields of the adrenal cortex and the sex glands are in intimate proximity.

Contribution to the Study of Socalled Cardiac Infantilism: Its Endocrine Pathogeny.—G. Bickel, E. Frommel and J. Hess (*Revue Française d'Endocrinologie,* February, 1924), hold the view that infantilism, in spite of the many distinctive forms under which it has become customary to describe it, is merely endocrine really in etiology, or else of general systemic nature. Cardiac infantilism, therefore, signifies nothing more than a deficient growth of the entire organism where congenital lesions of the heart exist in more prominent degree than those of other organs. They record such a case and show that in it the pituitary, thyroid, and adrenal glands especially were abnormal in histological structure, as were the kidneys and other organs.

Studies on Compensatory Hypertrophy of the Thyroid Gland.—Leo Loeb and Edward E. Kaplan (*Journal of Medical Research,* September, 1924), conclude from the result of the work here reported that feeding of the anterior lobe of pituitary gland prevents marked or even moderate degrees of compensatory hypertrophy in guineapigs, the greater part of whose thyroid had previously been extirpated. This effect is not caused by an admixture of inorganic salts of iodine with the preparation, because iodine in inorganic form is unable to prevent compensatory hypertrophy in the guineapig. The question is suggested whether administration of anterior lobe of pituitary might not be of benefifit in the treatment of toxic goitre.

Review of Another Year's Work in Thyroid Disease.—F. H. Lahey of Boston, in a summary under this title (*Endocrinology,* May, 1924), records the conclusions that hyperthyroidism does not exist in the absence of increased basal metabolism rate and cures of hyperthyroidism are not accomplished without return of basal metabolism rate to normal; that minus degrees of basal metabolism rate may exist in patients free from clinical evidence of myxedema yet made subjectively better by raising the rate to normal with thyroid feeding; that multiple stage measures are life saving procedures in severe hyperthyroidism; that the moderate value of x ray treatment is more than outweighed by its disadvantages; and that thyroid surgery done in a general surgical clinic equipped for the care and study of these cases will show few failures to cure and a mortality rate rarely over and in most cases under one per cent.

Effect of Iodine Upon Gas Metabolism.—Paul Liebesny (*Wiener klinische Wochenschrift,* May 22, 1924) administered iodides internally and determined the basal metabolism. He found that the effect of iodine in large doses upon the metabolism in individuals without disease of the thyroid gland was not uniform. In cases of hypofunction in goitre cases the metabolism is increased up to normal. Cases with hyperfunction show a reduction in metabolism after the administration of small doses of iodine in a large number of cases. There are also cases which respond to such doses of iodine with an excessive increase in metabolism. In the latter cases the iodine medication should be reduced gradually. Hyperthyroidism and exophthalmic goitre should be treated with iodine only when the patients are placed under a constantly careful and reliable control of the energy balance.

Parathyroid Tetany.—L. R. Dragstedt (*Endocrinology,* September, 1924), by feeding special diets to parathyroidectomized dogs and by intravenous injection of large amounts of Ringer's solution, has been able to prevent the development of tetany in these animals. A similar result is attained by the administration of calcium lactate in large quantities. The effect is produced by checking bacterial proteolysis or putrefaction in the intestinal tract with the formation there of highly toxic protein derivatives. Parathyroid tetany is an intoxication and the toxic substances come chiefly from the gastrointestinal tract. Whether calcium supplies a specific physiological deficit in the organism or merely controls the syndrome of parathyroid tetany by its pharmacological action is uncertain. But tetany in pregnant dogs cannot be controlled by calcium, although it can be by Ringer's solution. It appears probable, accordingly, that during pregnancy poisons capable of causing tetany may arise elsewhere than in the intestines.

Goitre Prophylaxis in Switzerland.—According to Hans Eggenberger (*Münchener medizinische Wochenschrift,* July 18, 1924) iodine is not merely a remedy, but an element of nutrition in daily amounts of 0.00004 of a gram. It is an essential constituent of the thyroid secretion, which, when deprived of it, loses its vitally active principle. The effect of iodine in many ways resembles that of the vitamines. It is a converter, a catalyzer. It is subject to the same metabolic laws as chlorine. Insufficient supply results in disturbances whose first manifestation is hypertrophy of the secretory apparatus of the thyroid gland. The inhabitants of goitre districts receive an insufficient supply.

Further Observations on Feeding Interrenal Gland in Cases of Graves's Disease.—S. Shapiro (*Endocrinology,* September, 1924), studied the effects of feeding interrenal gland in twenty cases of Graves's disease, using fifty per cent. glycerol emulsion of fresh ox glands. The principal effects were rapid gain in body weight and improvement in muscle strength, rise of blood pressure, when lowered, to normal, temporary increase in heat production, and relief of abnormal menstruation. Diarrhea disappeared when improvement in general condition occurred. The author considers evidence to be rapidly accumulating that the interrenal glands exert an inhibitory or regulatory control over the thyroid and that a functional interrenal insufficiency plays a fundamental rôle in the development of Graves's disease.

Goitre of Adolescents.—E. Gold and V. Orator (*Wiener klinische Wochenschrift,* April 3, 1924) found that the goitre of adolescents is the actively follicular, proliferating parenchymatous type of goitre, which is almost entirely devoid of colloid. It is predominant in childhood up to the seventeenth year of life. At the period of maturity, on the other hand, the colloid goitre is met with most frequently, and beginning with the fortieth year the nodular goitre is the most common. The authors frequently found colloid in the parenchymatous goitres following the preliminary treatment with iodine. Histological and chemical investigations showed that a deficiency of iodine, in addition to endogenic causes, should be considered an important cause for the development of goitre in adolescents. The insufficient compensatory hypertrophy gives the thyroid in treatment a great advantage over the simple iodine therapy. Operative intervention should follow only mechanical indicatons. The postoperative treatment requires careful iodine or thyroidin treatment in order to avoid recurrences and hypothyroidism.

Goitre.—Robert McCarrison (*British Medical Journal,* June 7, 1924), in his discussion on simple goitre, asserts that there are two main factors on which the prevention and cure of goitre depend: 1, the general hygiene of the individual, and especially of the intestinal tract; and 2, the amount of iodine available for the needs of the thyroid gland and the organism generally. A recognition of the intimate interrelation between them will enable us to deal effectively with most cases of goitre, whether they be sporadic, epidemic, or endemic. It is not always necessary that the water supply should be bacteriologically impure in order that the bacterial conditions in the intestine favorable to the production of goitre shall be set up: constipation and imperfect drainage of the bowel may be equally effective in producing them; and if at the same time the food be poor in iodine, or relatively poor in it in proportion to other constituents, thyroid hyperplasia and goitre will be very prone to occur.

Where the water supply is impure and unprotected from pollution, as it is in endemic areas, the first step in the prevention of goitre should be the provision of a pure and protected water supply. Similarly, the first step in the prevention and care of goitre in the individual should be the establishment of a state of perfect hygiene of the bowel. Where despite these measures goitre arises, then it may be assumed that the intake of iodine in the food and water is insufficient, and the prophylactic use of iodine is indicated, as it is when these measures cannot be applied or as an adjunct to them. The method of prevention of goitre by iodine is simple, rational, and cheap, and consists in the administration of 2.0 grams of sodium iodide, in 0.2 gram doses, distributed over a period of two weeks, and repeated each spring and autumn. It is best given at those periods of life when goitre is most likely to develop, and the call for it is more urgent in the female than in the male sex.

X Ray Treatment of Hyperthyroidism.—C. W. S. Saberton (*British Medical Journal,* April 12, 1924), states that it is not as yet known how the x rays produce their effect and cure hyperthyroidism, but as the function of the gland apparently becomes normal again it is highly probable that, apart from any local action such as thickening of the intima of the bloodvessels and an increase in the fibrous tissue elements of the gland, other changes occur which affect or modify the quality or quantity of the gland secretion. Radiating so vascular an organ as the thyroid may produce changes in the blood serum which may also influence the gland. It seems highly improbable that the radiation can cause myxedema. The author stops the radiation before the heart frequency comes down to normal, as the effect of the radiation is cumulative and continues for some weeks after actual treatment has ceased. Some patients who have still symptoms of hyperthyroidism on completion of their first course of treatment present themselves some few months later without any symptoms of the disease. Radiation treatment was not found to be satisfactory in cases in which symptoms of hyperthyroidism have supervened upon an old large parenchymatous, adenoparenchymatous, or cystic goitre. These cases should be referred to the surgeon, especially if there is pressure on the trachea. If the condition of the patient precludes surgery radiation treatment must be tried, as improvement in the patient's general health sometimes occurs, although the gland is not obviously reduced in size.

The Röntgen Treatment of Toxic Goitre.—E. W. Rowe (*Endocrinology,* May, 1924), pronounces the metabolism test the gauge for treatment in toxic goitre, calling it the quantitative estimation of thyroid function. The object of treatment, he says, is three fold—to reduce the output of thyroxin from the gland, lessen permanently the function, and to conserve the other organs of the body. The cleaning up of all focal infection is essential in every case. The general management is of major importance. The psychic control should be complete. The diet should be nutritious: a glass of milk three or four times a day is desirable. Rest and diet may entirely relieve mild cases, but lose their influence after the first advantage when metabolism is much disturbed.

For effective treatment surgery and the x ray are alone to be considered. It is impossible to compare in a practical manner the percentage of cures by surgery and the röntgen ray. They do not speak the same language. Few are completely cured by surgery. A master in this field has said that a successful operation only begins the treatment. The clinical signs may disappear and the metabolism rate return to normal, but there remains a subnormal individual whose capacity in life is restricted. At the Massachusetts General Hospital in comparing röntgen therapy and surgery it was found that in the third year after treatment the after results were the same. In röntgen therapy the improvement was gradual and progressive, with surgery there was a sudden marked improvement and a subsequent relapse.

The effect of röntgen rays is upon the thyroid gland, producing slow degeneration of the parenchymatous tissue, which is replaced by fibrous tissue. In the hands of an expert the dangers are small. The earlier the treatment, the more prompt the relief. The first improvement is seen in general bodily feelings in three or four weeks. Next will be noticed a fall in the pulse rate; then the weight begins to gain. Nervousness and insomnia improve. In about fifty per cent. the exophthalmos eventually disappears: in most cases it improves. Thyroid enlargement is the last objective sign to go. It is imperative that the one who directs the röntgen treatment should have full charge of the case. The general management of the patient is as important in x ray treatment as in surgery. Many failures occur because some one else directs and the specialist is the technician. The treatment of toxic goitre is major röntgenological work, the author repeats this with emphasis, and demands broad medical experience.

His method is to administer the rays over three areas, both lobes and the thymus. The presence of a more or less persistent thymus in sixty-five per cent. of cases of exophthalmic goitre renders its treatment imperative. The first four treatments are one week apart. In the second and third months they are ten days apart. Then there is usually a period of rest and subsequent administration is determined by the metabolism rate. Eighty kilovolts are used.

a distance of thirty-five centimetres, and an aluminum filter of five millimetres. Massive therapy is never used except in malignancy.

The indications for röntgen treatment are 1, all exophthalmic goitres not at too high a metabolic reading, although x ray treatment may be started cautiously in those much too high for surgery; 2, to prepare for surgery by reducing the activity of the thyroid; 3, after surgical failure; 4, adolescent goitre not responding to rest; 5, adenomatous goitre with toxicity; 6, carcinomatous degeneration accompanied by toxicity after surgical removal. Contraindications are 1, colloid, cystic, and nodular goitre without toxicity; 2, goitre causing marked pressure in the neck without symptoms; 3, intrathoracic goitre.

An Analysis of Types of Goitre with Indications for Treatment.—E. A. Arn (*Endocrinology,* May, 1924) classifies goitres under the heads of, 1, colloid goitre; 2, thyroid adenoma, a, without hyperthyroidism and b, with hyperthyroidism; and 3, Graves's disease. Treatment of colloid goitre includes prevention by the use of boiled water only and by the administration of minute quantities of iodine. The latter may be accomplished, 1, by the use of iodized table salt; 2, by giving thirty grains of iodine each spring and fall; 3, by administering iodine tablets in schools; 4, by the inhalation of iodine; or 5, by administering thyroid gland preparations. Existing goitre may receive treatment with iodine or with animal thyroid extract. Warning is given against the use of any but small doses of iodine. Larger ones may produce rapid symptomatic cure, but almost certainly cause a degeneration of the gland, and repetition often leads to serious consequences. For this degeneration thyroid extracts are the best remedy.

Adenoma of the thyroid is often quiescent many years, then becomes rapidly toxic following acute infection, such as tonsillitis, influenza, and pneumonia, or it may be lighted up by the injudicious use of iodine. Operative interference should be avoided, if possible, and, when imperative, ought to be as conservative as may be. Adenoma with hyperthyroidism is marked by cardiovascular changes, rapid loss of weight, gastrointestinal symptoms, increased metabolism, and increased nervous excitability. Following partial thyroidectomy the metabolic rate rapidly returns to normal and the gain in weight is quite rapid. The results are not so good, if the toxicity has been excited by repeated courses of iodine. Clinically there are two types of exophthalmic goitre, one characterized by chronicity, running an even, usually mild course, and rarely developing a thyroid crisis, the other characterized by fulminating attacks induced by shock, fright, sickness, overwork, acute infections, and other causes. A certain percentage of cases seem to recover without treatment, while others run an acute course and terminate fatally in spite of all treatment. X ray treatment, the author thinks, should never be used except in hyperplastic cases. Surgery must be individualized. Statistics from various clinics indicate that seventy per cent. are cured by surgery, twenty per cent. are improved, and ten per cent. are not benefited or have recurrences.

Conclusions Based on a Study of Four Thousand Cases of Goitre.—Following Engelbach's classification, A. S. Jackson (*Endocrinology,* July, 1924) states some helpful diagnostic points. Ordinary colloid goitre has a soft globular feel and symmetrical enlargement: a normal metabolic rate confirms the diagnosis. Adenomas develop in neglected colloid goitres as a form of compensatory development. One in every four adenomas becomes toxic before the patient reaches fifty years of age. An adenoma is present an average of sixteen years before the onset of toxic symptoms. In adenoma the gland is symmetrically enlarged, and one or more nodular tumors may be palpated: in exophthalmic goitre the gland is enlarged symmetrically. In toxic adenoma acute crises do not occur; thrills and bruits are rare; exophthalmos is not seen, hypertension and a disproportionately high diastolic pressure are the rule; loss in weight and strength, tremor, nervousness, a moist skin, tachycardia, and palpitation occur as in exophthalmic goitre. A history of gradually disappearing goitre, chronic cough, choking spells, difficulty in swallowing, and increasing huskiness of voice is indicative of a substernal or intrathoracic goitre. Malignancy does not occur in cases of exophthalmic goitre. An adenoma is potentially a precursor of cancer and should be removed.

In exophthalmic goitre the onset of hyperthyroidism, unlike that of toxic adenoma, is acute, the average duration of symptoms being nine months. The disease progresses by acute exacerbations and periods of remission. Thrills and bruits occur in eighty per cent of the cases. Bilateral exophthalmos is observed in one of every two patients within three months of onset of symptoms. The pulse pressure is high, a low diastolic pressure being a very important diagnostic point. Muscular asthenia is most marked in the quadriceps group of muscles.

Laryngeal examination before operation will show partial or complete paralysis of one or both cords in one of every fifteen cases. From a mediocolegal point of view this evidence may prove important postoperatively. In exopthalmic goitre Lugol's solution reduces the metabolic rate preoperatively an average of twenty per cent., because of the proportionate clinical improvement the necessity for ligation is thus obviated in seventy-five per cent. of cases. Lugol's solution and ligation are not indicated in the treatment of toxic adenoma. Because of the numerous advantages of the novocain method of local anesthesia the author uses it in ninety per cent. of his cases. When the operation is finished, undetected bleeders may be found by causing the patient to cough and strain.

Influence of Toxemias on Thyroid Gland.—W. S. Bainbridge (*International Journal of Medicine and Surgery,* April 1924) discusses foci of infection of the thyroid and compares thyroid pathological conditions to those which produce abnormal mammary changes, viz., autointoxication. When the toxemia is removed the breasts become normal. In the same way, allowing for the difference in the gland structure, removal of a toxemia which has affected the thyroid may cause complete disappearance of the thyroid condition. He studies in particular the relation of intestinal stasis to thyroidism, and reports a series of case histories to illustrate the point that the thyroid reacts very markedly to toxins from the intestinal canal. In the milder types of thyroidism, and those types of hyperthyroidism which suddenly become acute under fright, nervous strain, etc., the mere removal of intestinal stasis or other toxic condition was sufficient cure. The goitre disappeared without operation or thyroid treatment. In the more severe types of thyroidism a combination, removal of the toxic condition, thyroid treatment, and sometimes operation, was found to effect the desired cure.

Idiosyncrasy to Adrenalin, With Reference to Its Employment with Local Anesthetics and in Goetsch's Test for Hyperthyroidism.—H. E. Symes-Thompson (*Lancet,* April 12, 1924) concludes that some people show toxic effects as a result of receiving a small dose of adrenalin, and that these effects are increased if certain local anesthetics are given simultaneously. Toxic manifestations from adrenalin might be eliminated in dental practice if dentists were to avoid stronger solutions of this drug than 1 in 100,000. Surgeons might escape such manifestations by giving a preliminary injection of a smaller dose of adrenalin than that which it is proposed to employ at the operation; and, in the event of an idiosyncrasy to adrenalin being found to be present, by employing a general anesthetic. It is preferable to use synthetic adrenalin rather than the natural product. The use of adrenalin is contraindicated when operating on patients with exophthalmic goitre. The practicability of using large quantities of a dilute solution of novocain may render it possible to discontinue the use of adrenalin with this local anesthetic. The Goetsch test should only be employed when the diagnosis cannot be established by other means; if it is decided to make the test, a smaller dose should be given first, as suggested in the case of projected surgical operations.

The Pituitary Factor in Menstrual Processes and Its Relationship to the Corpus Lutuem. — J. Hofbauer (*Zentralblatt für Gynäkologie,* January 19, 1924) states that, contrary to the prevailing opinion, the changes in the uterine mucous membrane, maturation of the ovarian follicle, migration of the ovum and the formation of the corpus luteum are not primarily due to the influence of the ovum but to impulses which originate from the pituitary body and the midbrain (the vegetative centre). The albumin of the degenerating ovum acts anaphylactically and therefore menstruation is an anaphylactic phenomenon. The extract of the corpus luteum acts like atropine, inhibits vegetative processes, and regulates the bleeding.

Medicolegal Notes.

TAXATION OF HOSPITALS—EXEMPTIONS

The Pennsylvania Superior Court, in the Appeal of Children's Hospital of Philadelphia, 82 Pa. Superior Ct. 196, holds that an addition to an existing hospital building while in course of erection and therefore not yet actually used for healing the sick is exempt from taxation under the Act of April 9, 1921, P. L. 119. The court said that while it is well settled in Pennsylvania that the right to exemption of property from taxation is based upon use, the Supreme Court has never held that an addition to a building which was in use as a place of public worship, a hospital or other purely charity is subject to taxation prior to the time when it is actually used for religious or charitable purposes. "While it is the use of a hospital plant which determines its character as a public charity, it would be sticking in the bark to hold that an addition which is being constructed to a building which is in actual use as a purely public charity is not a part of the institution. It is not to be considered independently of the main structure. It will increase its efficiency and facilities."

COMPENSATION FOR INJURIES ARISING OUT OF EMPLOYMENT

The Maine Supreme Judicial Court holds, Pennell v. City of Portland, 125 Atl. 143, that the superintendent of a city hospital was not an "official" of the city within the exception of the Workmen's Compensation Act, since he was subordinate to the overseers, his tenure was uncertain, and he was not required to take an oath or give a bond, and the position he held was not statutory nor established by municipal ordinance. The claimant was held entitled to compensation for injuries received while climbing a ladder to trim trees in the home grounds at the direction of two members of the board, the accident arising out of his employment

ACTION BY PHYSICIAN AGAINST EMPLOYER

In an action by a physician against an employer in which the jury found that the defendant employed the plaintiff to attend its disabled employee, and expressly and unqualifiedly undertook to pay for such services, the Maine Supreme Judicial Court held, Ferren v. S. D. Warren Co., 125 Atl. 392, that under section 10 of the Workmen's Compensation Act the defendant, without contract except as implied from its status as an assenting employer, was bound to furnish, or pay for, medical aid to an extent determinable by the Industrial Accident Commission. But the employer may bind himself by express contract to pay medical bills. Such contract is enforceable through the common-law courts. No Commission decree is necessary to give it binding force. Unless the contract expressly so provides, such decree ca not limit the extent of the obligation. A decree of t Commission in a proceeding by the employee was held i admissible, since it did not effect any obligation arisin from the express contract between the plaintiff and t defendant.

OSTEOPATH HELD AS PHYSICIAN IN CONNECTICUT

In a proceeding under the Connecticut Workmen's Con pensation Act, the single question was whether an osteopat chosen by the claimant to treat his injury, a strained bac causing temporary total incapacity, was a "competent phys ician or surgeon to attend the injured employee" in thi particular case, within the meaning of the Statute. "Eac case," the court said, "is to be determined by its own fact Undoubtedly certain diseases are incapable of treatment b osteopathic methods. The statute, we think, requires bot legal competency and competency in the particular cas On the findings Dr. Andrus was competent in both of thes respects. He was licensed to practise the healing art b the lawful, though limited, methods of osteopathy, and h was competent to treat the claimant in this particula case for the injury in question, and did treat it with suc cess."

It was held in view of Conn. Gen. St. 1918, Nos. 2864, 286 that Dr. Andrus being a licensed "osteopathic physician was a "physician" within the meaning of the Workmen Compensation Act. Towers v. Glider & Levin (Conn.) 12 Atl. 366.

ACUTE DILATATION OF HEART HELD AS ACCIDENT

In a proceeding for the death of a mine employee whos duty required him each night to go down into the mine p and look after the pumps, and whose body was found afte he had climbed a stairway leading ninety feet down to th pumps, a doctor who saw the body and talked with othe employees gave the opinion that death had resulted fro acute dilatation of the heart, superinduced by exertion i climbing up the stairs from the mine pit. The Pennsylvani Supreme Court holds, Watkins vs. Pittsburgh Coal Co., 12 Atl. 461, that, assuming the accuracy of the doctor's opin ion, an award of compensation was warranted. Althoug the sudden death of an employee while doing work whic calls for no unusual physical strain raises no presumptio of an accident, the court holds that rule cannot be invoke where duty requires the performance of an act causing fatal strain to a vital organ. "A claimant," the court sai "is required to show the death was accidental, but not th precise nature of the accident. It clearly appears the de ceased sustained a fall, and this may have caused death b a brain lesion or some other injury; so, in addition to th question of heart strain, the circumstances tend to suppor the finding of an accidental death."

NOTICE TO EMPLOYER BY PHYSICIAN OR HOSPITAL SELECTED BY EMPLOYEE

The Rhode Island Workmen's Compensation Act pro vides that an injured employee shall have the right to selec a physician or hospital and that "the employer shall becom liable to such physician or hospital for the reasonable fee for such treatment," provided written notice is given by th physician or hospital to the employer within seven days afte the beginning of the services. The Rhode Island Supreme Court holds Harding vs. Imperial Printing & Finishin Co., 123 Atl. 81, that, while the employer does not becom directly liable to the physician or hospital unless notice i given and the claim is presented as provided by the act, i was the intention to permit the employee to recover afte he had personally paid for the services.

LOCUM TENENS CONTRACT HELD VALID

The California Court of Appeal holds, Rossiter v. Thompson, 226 Pac. 866, that a contract between physicians under which one is to attend to the other's practice for a specified period for a percentage of the returns, is not illegal If a provision in the contract that the employer "shoul absent himself and abandon his practice" for the term o the contract is void under the California Code sectio 1673, as restraining him from practising a lawful profession it would not invalidate the entire contract, the remainder of the contract being complete in itself, and not dependent upon the objectionable feature.

Syphilis of the Anus and Rectum

CHARLES J. DRUECK, M.D.
Chicago

Syphilis has been recognized and studied throughout the centuries, and many supposed causes have been described, but since Schaudinn and Hoffman in 1905 discovered the Spirocheta pallida much new knowledge has come to us. The infection, beginning locally, soon becomes generalized, with widespread evidences of concentration of the spirocheta in those areas. At the anus and within the rectum these changes may easily be mistaken for other diseases. Tumors of various sizes and ulcers of different degrees of depth when seen at the anus or within the rectum are often confusing, particularly to those who see but few cases of rectal disease and who, perhaps, think hemorrhoids, irritable ulcer, fistula and cancer the only disturbances of this region.

About the anus may be found the same skin syphilides as occur elsewhere, but all eruptions are modified in appearance by the action of the heat and moisture and the rubbing together of the buttock cheeks. The possibility of syphilis as an etiological factor must always be in mind. The discovery of the spirocheta, the Wassermann test, the new organic arsenic compounds, the use of the dark field microscope and the employment of spinal punctures for diagnostic and therapeutic purposes are additions to our knowledge of syphilis, the ultimate effect of which it is at this moment impossible to gauge.

DIAGNOSIS.

Any suspicious lesion should be examined for Spirocheta pallida and a Wassermann reaction sought in the patient's blood and spinal fluid, and be it remembered that a negative result of either or both of these examinations does not assure us that the lesion is not syphilitic. All of the morbid changes of the several stages of syphilis may appear at the anus and rectum and it is therefore vitally important that the examiner wear gloves when exploring these parts.

The definite diagnosis in the early primary stage before the spirochete has spread to the lymphatic system near the primary lesion and before the serological reaction is positive is the one and only time that, taken advantage of, may lead to success; and it is the time for action, instant and effective. This is the time for radical cure if such is possible. An injection of arsphenamine here can put an immediate end to infectivity of the case. A complete sterilization seems possible here, and the suppression of the biological and serological evidence of the disease is possible and possibly probable.

The dark field examination must be routine in every suspicious case, and a careful search made for spirochetes. When the antiseptics are applied, especially mercurials, the finding of these organisms is difficult or almost impossible. Because of this no mercurial dressings, or better still, no antiseptics, should be applied to any lesions until the examination for Spirocheta pallida has been made, and if any have been used, it should be made a routine to irrigate thoroughly with physiological sodium chloride solution and to apply a wet dressing of the solution for twelve hours or more before examining for Spirocheta pallida.

The surface of the lesion is wiped with a cotton sponge to remove superficial organisms. The wound may be rubbed or teased lightly, but one should not cause bleeding; just an oozing that will give serum to transfer to a new clean slide and slip should be produced. Immersion oil is put on both the under surface of the slide and upper surface of the cover. This will give a continuous airless medium from dark field to objective. A focus with fine adjustment should be secured until one gets a dark background with the glistening moving particles in white rings. Then a search for the twisting spirocheta may be instituted.

Syphilitic ulcerations at the anus may heal without deformity, but within the rectum syphilis always permanently incapacitates that organ, sometimes only partially and in other instances completely destroying its function. This deformity of the rectum is augmented by the constant irritation and infection from the feces as they pass.

Some time ago a young woman with a painful ulcer at the anus consulted me. She had suffered from constipation for several years and had frequently used an enema. Her physician had treated the ulcer with local applications and later by operation, but only made conditions worse. A phagadenic chancre was later diagnosed, and subsequent history proved this to be correct. We afterwards found how this woman was probably accidentally infected by using a borrowed fountain syringe. There was nothing unusual in her case except the location of the initial sore, and it is mentioned here because the rec-

Copyright, 1925, by A. R. Elliott Publishing Company.

tal expression of syphilis is not a frequent finding and may mislead, because the early ulcers may be mistaken for irritable ulcers and the later ones for tuberculosis or cancerous necrosis. Syphilitic new formations are frequently considered malignant. I also speak of this patient because positive evidences of chancres at the anus or within the rectum are usually evidences of unnatural coitus, but they are not always so, and the possibility of infection by means of toilet articles, a syringe tip, clothes, towels, or a bathing suit, is always to be borne in mind, as also the danger to surgeons of infecting their fingers through cuts or abrasions when examining or operating upon a syphilitic patient.

The same chancres, rashes, ulcers, and new formations may be found about the anus as occur in similar histological structures, in other parts of the body, but their clinical picture is modified by conditions peculiar to this region, because of the superimposed infection by intestinal microorganisms, the constant abrasions of the surface by the feces and the irritation of the intestinal secretions. Syphilis is seen here at all ages, in the inherited or acquired types.

CHANCRE

Chancres on the skin about the anus are dependent upon an abrasion being present at the time of exposure to infection. Within the rectum the mucous membrane may also be directly infected. The abrasion in the skin or mucosa may heal in a few days without any visible scar and later (after one to four weeks), the chancre appears at the same site (Fig. 1).

FIG. 1.—Chancre at the anus with *plaque porcelaine*.

Chancres at the anus occur frequently enough to be always thought of when an ulcer is seen at or about this opening. Its existence in men is almost positive proof of sodomy, but in women it may occur by accidental contact with the male organ or from vaginal discharges. The chancre may occur on the skin near the anus, between the radial folds or on the mucous membrane in the anal canal. On the free skin it resembles in appearance a chancre situated elsewhere, but when located between the radial folds or at the anal border it closely resembles an anal fissure. The differentiation is not easy, especially if seen before induration has developed about its base. It begins as a tiny vesicle accompanied by thickening or infiltration of the skin. Later the blister turns brown, and as the scab separates it leaves a shallow ulcer. The surrounding ring of induration always persists. Chancres, like other ulcerations in this region, vary considerably in the pain they cause, some patients being more sensitive to pain than others. Also the degree of pain of any ulcer depends upon its depth. If the chancre is situated out on the skin, away from the anus, it may cause only slight discomfort, and also if at the anus, provided it involves only the mucous membrane, but if it goes through the mucosa and especially if it involves the musculature, either by ulceration or by the fixative leucocytosis about the ulcer, it is certain to be painful. If the induration surrounds the muscle fibres it immobilizes them and by squeezing the fine nerve fibres produces the same sensation as an exposed filament. The chancre in the young woman referred to above was quite as painful as an irritable ulcer.

Chancre at the anus is more frequently observed than within the rectum. Its clinical course at the anus is the same as chancre elsewhere, and on healing there remains a small bluish white scar which is difficult to find later. For this reason the diagnosis often cannot be made afterwards. In other instances the hard contracting scar may cause stricture (5).

Chancre within the rectum is rarely seen because it may occasion little discomfort, only a slight discharge, and may disappear spontaneously. The ulcer has the usual chancre appearance—round, indurated, with sharp raised edges slightly undermined. If it develops on a prolapsing internal hemorrhoid it may be mistaken for a traumatic ulcer. At times no definite ulcer can be discovered, but rather a diffuse proctitis which is evidenced by the occurrence of diarrhea with bloody, mucous stools.

The enlarged inguinal and sacral glands can always be found and are valuable differential information.

SECONDARY INFECTIÓN

In the secondary stage of syphilis we find two forms of ulceration: 1. The mucous patch. 2. The large ragged ulcer, a sequence of necrosis produced by the strangulation of circulation in the tissue surrounding the syphilides.

MUCOUS PATCH

When syphilitic papules are situated in regions where the skin is constantly warm and moist and subjected to friction or upon mucous membranes, they are more or less modified in their appearance, differing from the lesions found in other regions. In regions where there are opposed skin surfaces such as between the buttocks, around the anus, the inner surface of the upper thigh, the scrotum and upon the vulva, the papules show these changes (Fig. 2). Sometimes the papules appear in such profusion as to cause an erythema which might be mistaken for acute eczema. In a few days the papules break down through maceration and become grayish or yellowish white ulcers, irregular in outline and upon an indurated base. These ulcers may be single or multiple.

If multiple, each ulcer will preserve its form, even though it be close to another. The edges are not undermined and the intervening tissue remains healthy. When the vesicles rupture there is a thin, fetid discharge which keeps the parts wet and macer-

FIG. 2.—Showing the occurrence of mucous patches about the anus.

FIG. 3.—Syphiloma of the rectum, with condylomata lata.

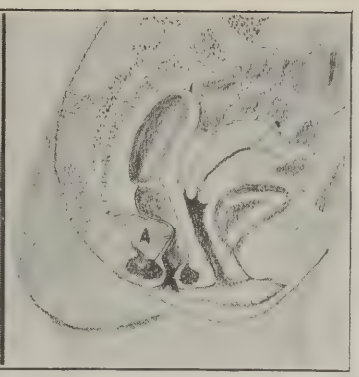

FIG. 5.—Schematic section of pelvis showing the location of the gumma, A.

ated. As the ulcers enlarge they become saucer-shaped, covered with a grayish white membrane, and are termed *plaque porcelaine*. The discharge and moisture of the opposed buttock produce hypertrophy and before the mucous patches are healed there develop broad, flat warts, the condylomata lata (Fig. 3).

Sometimes this hypertrophy is excessive, giving rise to large cauliflowerlike masses of vegetation covered with an extremely offensive secretion (vegetating or papillomatous syphiloderm).

When the mucous patch occurs upon the mucous membrane of the anus or rectum it varies from the size of a pea to that of the little fingernail and looks as if the ulcer had been lightly painted with silver nitrate.

CASE I.—C. 21, aged nineteen. For the past three weeks she had had a constant burning pain in the rectum at the anus, also a bloody discharge. Defecation was painful. On inspection there was found in the right posterior quadrant of the anus a bright red ulcerated area, extending from the anal canal to well out on the skin. A dense infiltration surrounded this ulcer and its edges were raised. There was also a large white area on the side of the right buttock. A macular eruption was found on the patient's upper body. The diagnosis was syphilitic chancre at anus with *plaque porcelaine* on buttock (Fig. 1).

ULCERATIONS SECONDARY TO OTHER SYPHILIDES

When the mucous patch appears there develops surrounding congestion which interferes with the local circulation, and sometimes the tissue sloughs away. This may happen with any syphilitic eruption about these parts, i. e., papular, macular, pustular or the small moist papules that appear at the anal folds, on the inner sides of the thigh, or about the genitals in any case of syphilis regardless of the location of the chancre. The resulting ulcers are gangrenous, gray in color, irregular in outline and ooze blood on slight touch.

There is a tendency to induration of the edges of the ulcer and to extensive stenosis of the rectum. This stage of the disease may frequently be mistaken for tuberculous ulcers, and vice versa. Spirochetæ are present in all these lesions which are therefore sources of infection.

Within the rectum the cellular infiltration and induration produce an edema of the mucous membrane. This swelling increases friction, and necrosis is produced usually in several places. The ulcers are regular in form, circular in outline, with clear edges, and usually the whole trouble is confined to the mucous membrane. If seen early they are amenable to treatment and may heal with little resulting scar.

As has been mentioned above, these ulcers cause few symptoms and therefore often go untreated until they have enlarged both on the surface and in depth, and until they may have extended through the deeper coats of the rectum and even into the pelvic structures. If they are on the anterior wall of the bowel, the peritoneum may be opened and infected; if on the posterior wall, the sacrum may be laid bare. If the patient also suffers from some other systemic disorder such as nephritis, tuberculosis or anemia, the ulcer may spread out almost unlimitedly. Kelsey, quoted by Tuttle, reported a case where the whole rectum was circled. The favorite location for these ulcers is about one inch above the sphincter, but they are found less frequently higher up, even to the colon.

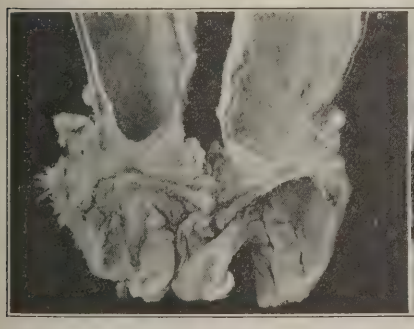

FIG. 7.—Complete stricture (syphilitic) which is annular and resembles cancerous stricture.

FIG. 10.—Congenital syphilis. Showing extensive destruction as a result of ulceration of papules.

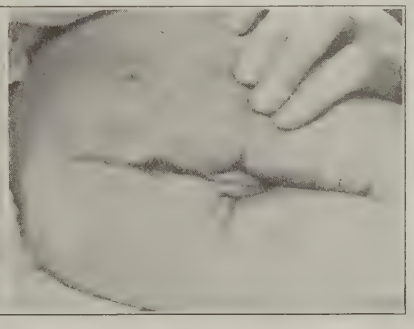

FIG. 11.—The same case of congenital syphilis as that shown in Fig. 10 after antiluetic treatment.

Fig. 4.—X ray photograph of patient in case C 23, showing the location of the gumma, A.

These ulcers are sluggish in appearance, with sodden surrounding tissues, and are usually chronic although not always. Occasionally one is phagedenic for the reasons already assigned. Ulcerating syphilides are likely to be confounded with tuberculous ulcers. Paget in his classical differentiation says they have sharp, well defined edges with level base. This is in contrast to the ragged, undermined and indurated edges of tuberculosis. If several of them coalesce, they appear as one large ulcer, or as a lobulated ulcer, but they do not encircle the bowel as do tuberculous ulcers. On the other hand, if tuberculosis has existed long enough to produce a number of ulcers in or about the rectum, or a large excavating one, we will find tuberculosis in other organs. There is considerable purulent discharge from the tuberculous ulcer. The syphilitic ulceration produces a thickened leathery feel to the bowel, but tuberculosis does not affect the elasticity of the rectum.

At this time the lymphatics are much enlarged and may be mistaken for abscesses or gumma. From these ulcers there is an abundant discharge of greenish pus, tinged with blood, and having a fetid odor, which is characteristic and different from that of carcinoma or the ordinary rectal abscess. Infection of the deep lymphatics may occur and end in abscess and fistula. Such fistula are often unresponsive to surgical treatment unless combined with antisyphilitic medication. If ulceration progresses to this advanced stage stricture of the rectum is inevitable.

Fig. 6a.—Syphilitic stricture showing pencillike calibre and the funnelshaped upper limit.

Fig. 6.—Classical syphilitic pencillike stricture. Lower end of rectum above internal syhincter shows a long smooth contracture of the lumen, without any filling defects showing or any fistulous channels. The picture looks like the pathology produced by a syphilitic process. No ampulla shows at all as canal does not expand enough to form an ampulla. Colon looks normal and shows no defects from sigmoid to cecum.

Late or tertiary changes about the anus and rectum appear as ulcers, gumma and fibrous hyperplasia which arise after all of the earlier evidences have disappeared. Trauma may excite active lesions on the predisposed soil of syphilitic infection.

MacCallum (4) says: "It will be observed in considering the development of the tertiary syphilitic lesions that they often arise in places where there were secondary lesions which had healed, and it has been suggested that they are the effect of the further growth of spirochetæ which had been left behind in the healing of the secondary syphilis. The

FIG. 8.—Syphilitic rectal stricture, which does not have a funnel-shaped upper extremity.

evidence is not entirely convincing in regard to this, although there are many well attested cases in which gummata appeared on the site of secondary lesions."

NODULAR SYPHILODERMA—TUBERCULAR SYPHILODERM

The nodular syphiloderm is characterized by patches of dull red or brownish red elevations varying in size from that of a small to a large pea, with a smooth or slightly scaly surface, usually aggregated in variously sized patches or groups either without definite arrangement or, what is common, arranged in circles or crescents. Although such patches may be annular from the beginning, they also frequently arise through the absorption of the centrally situated lesions, while new nodules are added to the circumference. The nodules may undergo absorption after a month or two, leaving pigmented atrophy of the skin, or they may ulcerate forming patches made up of a number of small round punched out ulcers covered with crusts. These ulcerating patches are often crescentic or reniform in shape, advancing on the convex border and healing on the concave side, or they may form extensive serpiginous figures which ulcerate and crust over, and frequently involve large areas in the course of month or years, producing extreme destruction of the skin followed by scarring of a characteristic kind. There is usually but one such patch upon the body, although there may be several. The nodular syphiloderm is usually seen two or three years after infection, although quite exceptionally it occurs in the late secondary period, when the lesions are likely to be much more numerous than the latter eruption, although never generalized and symmetrical. It commonly occurs ten years or more after the initial lesion.

The course is a chronic one, the patches slowly extending and lasting for years unless removed by treatment. Usually there are no marked subjective symptoms. Even when extensive ulceration occurs, there is little or no pain, but exceptionally there may be severe pain upon movement or when the individual sits or lies down.

Diagnosis.—The nodular syphiloderm is usually recognized without difficulty, the only affection for which it is at all likely to be mistaken being lupus vulgaris. The former is almost always a disease of adults, the latter begins as a rule in childhood; the former frequently shows an annular or crescentic arrangement, the latter infrequently does so; the syphilitic affection spreads rapidly and in a few months is as extensive as lupus is in as many years. When lupus recurs it does so in the midst of the cicatrices, whereas, the nodules of syphilis are found at the margins of the scars.

Gumma.—The gumma is usually a manifestation of the late tertiary stage of syphilis, but it may occur in the late secondary stage or even, very occasionally, in the early secondary stage, when as Hartzell (11) says it is usually regarded as a symptom of socalled precocious syphilis. Gumma occurs quite frequently upon the buttocks and thighs and it may develop in the mucosa of the anus or rectum in the connective tissue of the bowel or of the ischiorectal fossa.

Gumma may be single or multiple, although Johnson (2) says the isolated gumma is rare. It begins as a small firm subcutaneous nodule about the size of an enlarged lymph gland, which, as it enlarges, becomes adherent to the overlying skin which, at first, is of normal color but later becomes red and slightly elevated. It grows rapidly and in the course of a month or two it may be as large as a hen's egg. The skin becomes stretched, bluish in color, and finally gives way, a viscid bloody fluid escaping through the

FIG. 9.—Syphilitic rectal stricture.

opening. Upon palpation the gumma feels like a pea or marble beneath the surface. If the tumor is large it may be mistaken for a myoma.

Case II.—C. 23 presented a large single gumma. This woman, a seamstress, aged forty, had not been able to work for a year because of pain in the rectum. She had daily bowel movements which were streaked with blood or mucus, but the evacuations were not particularly painful. She had not lost weight. On digital examination there was found about two inches above the anus a large, hard, round lobulated tumor about two inches in diameter. It was between the rectum and the coccyx and was firmly fixed. It was not painful and could easily be mapped out. No fluctuating spots were found (Fig. 4). A röntgenogram clearly showed the growth. A clinical diagnosis of gumma was made and under treatment it promptly showed improvement. Fig. 5 is a schematic drawing of Case C. 23 showing the position of the gumma A.

Sometimes the outline is well circumscribed but in other instances an area of diffuse fibrous hyperplasia infiltrates around about, forming a firm, rather ill defined dusky red or bluish plaque.

Softening and caseating necrosis develops in the centre of the gumma and the tumor becomes soft and elastic. Later several round openings appear from which a viscid fluid is discharged. These openings may remain discrete or several of them may fuse into one sharp cut punched out ulcer having considerable depth, sometimes extending down to the deeper tissues, and if untreated the ulcer slowly extends in depth and circumference. Eventually the whole indurated region may break down into a large serpiginous ulcer. If the early openings of a gumma be into the rectum fecal matter may be forced into the pocket and an ischiorectal abscess be formed later. Many fistulæ may thus appear extending out into the skin or invading the bladder or vagina. Occasionally the gumma instead of following the above course will disappear by absorption without ulceration.

The early appearance of the growth closely resembles cancer in that it is nodular and freely movable in the subcutaneous connective tissue. Later when extensive gummatous infiltration and ulceration occurs about the perineum or the female genitalia, the lymphatic circulation may be greatly interfered with and a condition of fibrous thickening with papillomatous growth may arise resembling elephantiasis.

The gumma is usually without pain in its earlier stages, but when the ulceration has occurred there may be constant sharp tearing pain whenever the tissues are subjected to stretching or movement.

The diagnosis of gumma presents little difficulty when seen in the ulcerative stage, its circular shape and punched out appearance, the absence of pain except on movement of the parts and often the presence of old syphilitic scars elsewhere are quite characteristic. In the earlier stages before ulceration has occurred it may be mistaken for fibroma, lipoma, sarcoma or tuberculous gumma, but its comparatively rapid growth is distinctive. When uncertainty exists regarding the differential diagnosis the patient should be given the benefit of a short course of antiluetic treatment before subjecting him to a serious and mutilating operation. The Wassermann reaction may be negative in late syphilis and its presence only proves that the patient is a syphilitic subject and not that the ulcer is of necessity syphilitic.

If the gumma is incised the wound remains unhealed and later becomes surrounded with extensive, dense scar tissue. Finger and Landsteiner (3) have shown that gummata contain living spirochetes which can produce infection in another animal.

The proctitis associated with the ulceration and

Fig. 12.—Syphilitic ulceration at anus.

cellular infiltration occasions a mucopurulent discharge, a feeling of fullness in the rectum and sphincteric tenesmus. When ulceration is marked a deep burning pain is complained of. Each defecation is painful and is usually followed by bleeding.

Fibrous infiltration of the rectal coats without distinct gumma formation but instead a diffusing through all the structures of the bowel, particularly the mucosa and submucosa, sometimes occurs. Multiple syphilitic nodules arise in the mucous membrane, usually just within the rectum proper, and spread upwards sometimes so far as the sigmoid flexure or colon. This is a hyperplastic proctitis, a diffuse and wide infiltration of the whole wall of the gut but especially the submucosa, with mononuclear and epithelioid cells. It soon breaks down into extensive ulcers which may even surround the rectal lumen. A foul discharge is present and defecation is painful. Numerous fistulæ develop, some of which extend widely out on the buttock into the vagina or urethra. Pain and tenesmus are constant because ulceration is extending in one place while cicatrization goes on in another. Alternate constipation and diarrhea occur and the rectum is dilated and hypertrophied above the ulcerated area. Later the dense scar formation about the healing constricts the lumen of the gut and obstruction arises. Although this condition is exhausting the patient usually dies of some other cause for which this chronic poisoning prepares the way.

Case III.—A woman, aged forty-two, married, two children, no history of syphilis. About three years ago she noticed a hardness of the perineal body. The vagina seemed hard and stiff; her physician gave her local treatment without success. When

I saw her she suffered from obstinate constipation which was gradually getting worse, and a tentative diagnosis of carcinoma had been made. On examination the anus was found in its normal position. The skin of the perineum and about the anus was rough and wrinkled, dry and thickened, but not sensitive. On attempting digital examination I found the rectal wall hard, rough and tight about the finger, making introduction painful. The narrow, cylindrical three quarter inch rectoscope was introduced with difficulty. The hardness and fullness of the tissue was greatest at the anus and shaded away for a distance of five inches within the rectum. The examination was painful, and although it stretched the tissues considerably it did not cause any bleeding. A positive Wassermann was obtained.

Syphilitic stricture of the rectum.—Just how frequently syphilis causes stricture of the rectum is a moot question. Some authors assert that all nonmalignant strictures are syphilitic, while others are equally positive that strictures result from any ulcerative changes regardless of its type or etiology. At any rate we do find that syphilitic stricture may follow any syphilitic ulcer as chancre, secondary ulcer, or broken down gumma and that it has certain peculiar characteristics. The Wassermann reaction will, however, help us to decide definitely for or against lues in a given stricture. Clinically, however, it is sometimes impossible to say that a given stricture is or is not syphilitic. Of course, once ulceration occurs and septic infection is added, the picture is so confused that a microscopic examination of a piece of the tissue may be necessary for diagnosis. The chancroid, though not syphilitic, is a close relation and frequently produces a serious form of stricture.

The discharge of blood, mucus or pus of which many syphilitics complain during the secondary stage, is often attributed to the mercuric remedies administered and the probability of the presence of mucous patches or ulcers is forgotten. We do not see stricture patients during the latent or infiltrating stage because they do not consult a physician until they are suffering from stenosis of the rectum.

Histologically we find in the syphilitic stricture a chronic inflammatory formation about the bloodvessels and within their walls. Especially is this found in the arteries. This obliterating endarteritis is the same as found in any syphilitic lesion.

The infiltration and thickening of the mucous membrane about the ulceration or about the minute gummatous deposits in the mucous membrane imparts a stiff, rough, leathery character to the rectal wall and thereby limits and lessens the distensibility of the rectum. A sanious and mucopurulent discharge fills the rectum. Later when the ulcer may have healed the mucous membrane remains dry. The cicatrix is blue white, dense and hard and usually presents some ulceration at its upper extremity. Syphilitic ulcers are inclined to follow the course of the lymph and bloodvessels, and as that direction in the rectum is lengthwise the contracted portion is usually tubular instead of sharply annular as we find in the inflammatory stricture. This condition may extend from the anus to the colon although most syphilitic strictures occur from one to three inches from the anus, the more recent part of the stricture with its infiltration and proliferation is frequently the most obstructive. Ulceration may also be found below the stricture and from these ulcers fistulæ lead to perirectal abscesses or open externally on the skin or into the vagina or urethra.

When decided stricture occurs low in the rectum constipation alternates with diarrhea and the passage of ribbon shaped or broken stools.

Differential diagnosis.—The differentiation of syphilitic from tuberculous, dysenteric or malignant strictures is a most important factor. Syphilitic strictures usually are long, funnel shaped contractions with blue white cicatrices about the ulcers. The edges of the ulcer are never undermined but rather craterlike. In some instances these dense white scars can be plainly seen through the speculum in the tissues of the rectum just below the stricture.

Fig. 6 shows the tightly contracted rectal lumen of a syphilitic stricture.

Case IV.—This woman contracted syphilis seven years ago. For the past year she had had pain in the rectum and a purulent sanious discharge. The bowels were always constipated. On digital examination the finger, at a distance of one and one half inches from the anus, came to a solid impassable stricture. The rectum below the stricture was hard and nodular. The patient had several fistulæ leading into the vagina and others out onto the skin. These were tender as the digital examination was made. The patient had been on intensive antisyphilitic treatment for some time, and, although her general condition had much improved, the obstipation was still a serious matter and an abnormal anus has been advised.

Here is appended the röntgenologist's report of Fig. 6.

Radiological findings.—Lower end of rectum above internal sphincter shows a long smooth contracture of the lumen, without any filling defects showing or any fistulous channels. The picture looks like the pathology produced by a syphilitic process. No ampulla shown at all as canal does not expand enough to form an ampulla. Colon appears normal and shows no defects from sigmoid to cecum.

Not all syphilitic strictures are long and pencillike in character. Sometimes the pathology is limited to a small area and the stricture is more annular in character, as in Fig. 7. Here the differential diagnosis from the physical findings was not possible.

The patient was first seen when acute obstruction had developed and a laparotomy was performed. When the abdomen was opened and the sigmoid was lifted up it was noted that the hyperplasia seemed largely on one side of the bowel. Resection was performed and subsequent microscopical examination showed it was not malignant.

As has already been mentioned some of the obstructive symptoms result from the inflammatory swelling about the ulcers. This infiltration and swelling of the mucosa is not syphilitic but rather a reaction to the local streptococcic infection. As the luetic endarteritis subsides gummatous deposits resolve or the ulcers heal under treatment, the swelling of the mucosa lessens and sometimes the obstruction is relieved.

Case V presents such a condition: About one year ago this woman began to have constant pain, of

a cutting character in the rectum, with rectal tenesmus. Since then she passed blood and pus every day. During this time she lost fifteen pounds in weight. She was twenty-six years old. A positive Wassermann was obtained. She was placed on antisyphilitic medication and immediately began to improve. Her appetite returned. She had formed fecal masses which were evacuated without suffering and she improved in general physical appearance although the radiograph of her rectal stricture was still unchanged.

In this case (Fig. 8) the upper end of the stricture is entirely different from that of Fig. 6. The upper limit of the strictured portion of the rectum ends abruptly and the normal elastic rectum continues. But the distinctly tubular stricture will be noted. Nothing surgical was attempted, the woman improved steadily until she became quite comfortable and finally left our observation.

The irregular outline of the upper end of the stricture is very suggestive of the ragged outline obtained in radiographs of cancer of the rectum.

Case V (Fig. 9) is another syphilitic stricture which might easily be mistaken for a malignant growth because of the ragged appearance of the lower end of the patulous bowel, but on closer observation it will be noted that the irregular outline is that of the coccyx situated directly behind the rectum. This patient, aged twenty-seven, had suffered pain in the left loin for the past six years. For the past year she has had pain in the rectum, quite obstinate constipation and the discharge from the anus of blood and pus. A three plus Wassermann reaction was obtained.

PROGNOSIS

The prognosis in all strictures must be guarded until the patient has been under treatment long enough to weigh the various factors in each case.

The inflammatory tumefaction which is a part of the endarteritis will subside under antisyphilitic treatment. The luetic ulcers also will heal and this may relax the obstruction sufficiently to make the patient comfortable and perhaps relieve the constipation. Such a patient is symptomatically cured.

Where the obstruction results from cicatricial contraction as in Fig. 6, relief is not obtained and an abdominal anus or a resection may be required at any moment as in Fig. 7.

When the stricture is low in the rectum and the fibrosis involves the sphincters, atrophy of those muscles frequently produces fecal incontinence.

CONGENITAL SYPHILIS

Congenital syphilis (infantile or inherited syphilis) presents much the same eruptions and ulcers as the acquired form, with the absence of the initial chancre and the several lesions are not in the usual orderly stages. Hartzell says: "The type of eruption is more or less influenced by the period at which infection has taken place, i. e., whether it has occurred at the moment of conception or at an earlier or late period of the pregnancy. The later in the pregnancy the infection takes place, the more nearly the eruptions approach in type those of acquired syphilis. About the anus of a young infant the skin changes are more hypermic and less infiltrated than those of the adult and may be overlooked or mistaken for a simple skin irritation due to uncleanliness.

The earliest manifestation of syphilis in babies is an erythema or macular dermatitis accompanied by shallow fissures about the anus. This often appears about the third week but may appear the first week or be delayed as late as the sixth or eighth week. The red patches, varying in size from that of a pea to a fingernail, gradually become brownish red or copper color, and do not wholly disappear under pressure, owing to the presence of slight pigmentation. There is a slight degree of infiltration which produces thickening and elevation of the skin and a tendency to slight scaling.

The anal mucous membrane is fragile and brittle and shallow fissures are easily produced by dilating the anus. These fissures soon become infected and emit a thin seropurulent, and very fetid discharge. At times these little fissures extend up into the anal canal. As these ulcers heal they leave radiating scars (socalled rhagades).

About the anus, on the scrotum and thighs moist papules or flat condylomata may be found. Frequently these ulcerate, sometimes very deeply, and extensive destruction may result (Figs. 10 and 11).

All of these changes may occur within the first few months of life and may be mistaken for the chafing that results from contact with feces and urine, but the latter condition is never associated with the numerous small shallow anal fissures found in syphilis.

SYPHILIS OF NERVOUS SYSTEM

Syphilis of the central nervous system (tabes) may be evidenced early by a deficient sphincteric innervation. This relaxation of the sphincter muscle may be evident before the knee jerk is lost. Whenever on digital examination of the rectum the sphincter fails to squeeze down tight on the finger and if no evidence of trauma is found always think of syphilis. The anus may even remain patent a moment or two after withdrawing the examining finger.

TRAUMA AND LATENT SYPHILIS

Latent syphilis may in cases play an important rôle as a factor in the immediate and late consequences of trauma. In a normal patient a minor injury or surgical operation on or about the rectum usually heals by primary union although moisture, warmth and hordes of bacteria are always present, and the wound is covered with feces at each defecation. It is not definitely known why syphilitic lesions are likely to appear at the site of trauma, but it would appear as if the body tissues, continually in contact with certain bacterial flora, develop an amount of local resistance which enables them to exist unharmed. Thus ordinarily the mucosa of the lower bowel may be scratched by bits of sharp waste matter, may be irritated by acid stools, may be subject to the ordinary trauma, incidental to defecation, with little consequence. In a syphilitic, however, this barrier of local resistance is broken and the reparative processes are in abeyance. As a result we have a series of rectal conditions, ulcers, fissures, abscesses, fistulæ and proctitis, not truly luetic but engrafted on a syphilitic constitution.

Also the infliction of trauma may produce a *locus minoris resistentiæ* and serve to activate dormant spirochetes. This view is sustained by the following observations. Warthin has demonstrated the spirochete in many organs of latent syphilitics coming to

necropsy. Spirochæta pallida has been found in atrophic and pigmentary remains of syphilides long after their involution. These organs may be found in the scar of chancre long after the sore has healed. Neisser found spirochetes in the skin of syphilitic patients in which there was no local tissue reaction.

Before the spirochete had been discovered, Neumann (6) recorded the persistence of perivascular cell infiltration of the papillary bloodvessels long after the disappearance of the syphilitic papules.

Spirochetes from the blood may be deposited at the site traumatized. Although it is exceptional for these organisms to be recovered from the blood of patients with tertiary syphilis, cases have been reported in which the organisms were demonstrated in such instances. Uhlenhuth and Mulzer (7) report such findings.

(To be concluded)

The Possibility of Immunization of the Tissues of the Nose, Throat and Ear by the Use of Vaccines Applied Locally

HAROLD HAYS, M.D., F.A.C.S.
New York

During the summer months of 1924, I had the matter of local immunization of tissues brought to my attention. Credit should be given to Dr. Walter M. Kraus for supplying me with the French literature and vaccines. Professor A. Besredka of the Pasteur Institute had recently made known his results in the prevention of typhoid fever. His experiments prove conclusively that typhoid vaccine can be administered by mouth and give an immunization which will last for a considerable length of time. It is impossible to go into the details of Professor Besredka's experiments here. Suffice it to say that he gave the vaccine to thousands of persons who were exposed to typhoid fever and who refused to take the hypodermic inoculations and was able to avoid the spread of the disease. Besredka observed that the intestinal mucosa would take hold of the vaccine better if there was first an ingestion of bile. Therefore the person given the vaccine takes a preparation of bile one hour before breakfast each morning and then takes a tablet of desiccated killed typhoid bacteria a half hour later. This will give an immunization for a year.

After I had taken this vaccine myself and had read the literature, the possibilities of using vaccines locally on the tissues of the nose, throat and ear immediately presented itself. Nothing could be simpler than making up a large mass vaccine, with no attempt to isolate special bacteria, and applying it locally to the tissues. Such a vaccine not only would conform to the vaccine used by Besredka but at the same time there was every possibility that the broth in which the bacteria grew, would develop some bacteriophage.

After the first few cultures were made, it was deemed wise to isolate the bacteria by spreading them on blood plates in order to check up on the predominating bacteria found in nose, throat and ear infections. Over two hundred vaccines have been prepared during the last few months. In the majority of them the streptococcus (one of several varieties which, often, could not be differentiated in broth cultures) was found either in association with the staphylococcus aureus or the micrococcus catarrhalis. This, by no means, indicates that these are the only bacteria found in these infections but that these bacteria predominate the growth in broth culture.

The method of obtaining the vaccine is simple. A culture is taken from the desired part. If the culture is to be taken from the nose, the sterile swab should be inserted far back or high up in the middle turbinate region. It is immediately sent to the laboratory, where it is placed in a sugar bouillon and allowed to grow for forty-eight hours. The culture is then sterilized to the right temperature and put in a four ounce bottle. A few drops of tricresol solution are added to keep it from contamination.

METHOD OF APPLICATION

For the local immunization of tissues of the nose, throat or ear, the method will vary according to the part to be treated but the object in all cases is to place it as near the seat of infection as possible. Besredka reports many cases of osteomyelitis which have been cured by making a vaccine and applying it as a wet dressing over the diseased part. I had one case (in the service of a surgeon who was a friend of mine) in which there was severe osteomyelitis of the bones of the hand. A vaccine was prepared (streptococcus) and used as a wet dressing. Within a short time the infection cleared up although it had been going on for months.

For infection in the nose, the method of application is as follows: the nose is thoroughly cleaned out by means of alkaline sprays and douches. To the cleaned mucosa the vaccine is applied on thin strips of gauze or flattened cotton which are allowed to remain in the nose for one half to one hour. This treatment is given twice a week for four weeks. In the intervals between treatments, the patient is given some of the vaccine to use in the nose, either spraying it in or using a few drops of it twice a day with a medicine dropper. This is continued until the entire four ounces of vaccine is disposed of. In antral infections, the vaccine is placed in the antrum at one sitting through the puncture opening. For ethmoid infections (and this includes the cases of asthma) the vaccine should be placed high up against the ethmoidal cells (the Dowling tamponade).

For tonsillar or nasopharyngeal infections, it is best to place the vaccine as far back in the posterior

nares as possible. The assumption is that the absorption of the vaccines is through the lymphatics.

For conditions within the auditory canal, the vaccine is dropped into the canal and allowed to remain there for one half hour. The treatment may be given at home twice a day. For the slow healing mastoid wounds, the vaccine is dropped into the mastoid cavity at each dressing or may be applied as a wet dressing to the entire wound.

TYPES OF CASES TREATED

The types of cases which have been treated include the majority of the infections of the nose, throat and ear. Chief among these were infections of the nasal sinuses, especially ethmoiditis. There were three cases of asthma associated with an infection of the ethmoid cells. The ear cases include furunculosis, eczema of the ear canal, chronic suppuration from the ears and five cases of slowly healing mastoid wounds which ordinarily would have been Dakinized.

RESULTS

As we stated previously, about two hundred vaccines have been prepared and well over one hundred administered. In an analysis of one hundred and thirty-six cases, in a variety of nose, throat and ear conditions, ninety-five have shown a great improvement or cure. There have been only six absolute failures and these were in cases of ethmoiditis in which the pathology was sufficient to warrant operation. The author is not in a position to state the beneficial effects of the vaccine in cases of progressive deafness but he feels that an application of the vaccine to the eustachian tube on an applicator which can progress to the middle ear, will possibly result in an improvement of the condition of the tubal mucosa. The majority of cases for which a vaccine was prepared were cases of sinus infection, mainly of the ethmoid cells. If the vaccine is placed in the proper position—that is, high up in the ethmoid region, the results are most gratifying. But the type of case in which most striking results can be seen is in the child who is suffering from so-called repeated colds in the head during the winter months with a discharge of large amounts of mucopus. Almost all of these cases have responded to treatment and this is particularly interesting because these children will not submit to hypodermic administrations.

CONCLUSIONS

1. Reports of the local administration of vaccines for other conditions, such as typhoid fever, have conclusively proved that they will render an immunity.
2. The preparation of the vaccine is extremely simple.
3. The vaccine can be administered without any difficulty directly on the part of the nose, throat or ear which is infected.
4. The broth in which the vaccine grows possibly develops a bacteriophage which augments the effects of the vaccine.
5. Certain definite results have been seen in those infections which do not respond to ordinary antiseptics.
6. The local vaccine can be used on many patients who will not submit to the hypodermic injections of vaccines as usually given.

Trigeminal Neuralgia

FRANCIS C. GRANT, M.D.
Philadelphia

Typical trigeminal neuralgia is one of the easiest conditions to diagnose. Sharp, lightning, lancinating pain, coming on in paroxysms and referred to the peripheral distribution of the trigeminal nerve, the alæ of the nose, the upper and lower lips and the tongue are characteristic. The pain is stabbing, excruciating, unbearable, one of the most severe to which we are exposed. Movement of the face, touching the area supplied by the fifth nerve, hot or cold food in the mouth, a draft of cold air on the face, a sudden noise, is sufficient to cause a stab of pain when the sufferer is in the grip of an attack. In severe cases, fear of the pain prevents eating, washing the face, shaving or even talking, the poor unfortunate sitting perfectly still without moving a muscle lest a spasm result. These attacks come suddenly, causelessly, like a bolt from the blue, last for a time and then cease as abruptly as they began. Such an attack may last from a day to two or three weeks. In the interval there may be complete freedom from pain and the sufferer may be deceived into believing that his troubles are ended. But the pain almost inevitably recurs, the second and succeeding attacks being rather more severe than the first.

Three things are typical of the pain of trigeminal neuralgia. It is paroxysmal, epileptiform. It is referred to the skin surface in the peripheral distribution of the trigeminal nerve. The pain runs parallel to the nerve fibres and the lower jaw and does not run upwards or downwards across the three divisions of the trigeminus. With these three facts in mind it is fairly simple to distinguish between true trigeminal neuralgia of the major type and other pain in the face which may simulate it.

Trigeminal neuralgia is a disease of later life; its occurrence in patients below the age of thirty-five is rare. Males and females alike are afflicted. The incidence of one side of the face over the other is so slight as to be negligible. The second or third divisions are usually involved, the third more commonly than the second, the first more rarely so. If the pain occurs in two divisions, the combination most frequently encountered is the second and third.

The pain may be distributed in all three divisions at the same time. At present there are only two effectual methods of treating tic douloureux—alcohol injection into one or the other of the three divisions of the nerve depending on the distribution of the pain, and section of the sensory root of the trigeminal nerve behind the Gasserian ganglion. All other methods of treatment have been rightly abandoned. Drug therapy is useless. Curiously enough even morphine in large doses is of but little avail in relieving the pain in a major attack. If a patient suspected of having trigeminal neuralgia has become a morphine addict this fact alone should make us wary of confirming the diagnosis of tic without careful consideration. Injection of alcohol into or avulsion of the infraorbital and interior dental nerves has been replaced by direct injection of the second or third divisions at a point as close as possible to their exit from the base of the skull. The deep injections, when successful, are more permanent in their effects than peripheral injection or avulsion. The possibly bad cosmetic result of an operative scar about the face is avoided. In the case of pain in the first or supraorbital division, however, neither of these objections hold. It is not possible to perform a deep injection on the supraorbital nerve. Alcohol may easily be injected into the supraorbital foramen almost by sense of touch. Peripheral avulsion after operative exposure of the nerve is the procedure of choice in supraorbital neuralgia, for the scar in this procedure lies in the eyebrow and is entirely invisible.

Deep alcoholic injections are of much value from a diagnostic point of view. In any case in which the onset or character of the pain is not typical, alcoholic injection of the division in which the pain exists will determine whether or not the pain is due to actual involvement of the fifth nerve or lies outside the trigeminus. If alcohol injection produces peripheral anesthesia in the division attacked and if with the appearance of the peripheral anesthesia the pain in that area is relieved, then true major trigeminal neuralgia exists and avulsion of the sensory root will permanently relieve the suffering. But if following a successful deep injection of the second or third division, as shown by the peripheral anesthesia produced, the pain continues, then the pain is due to factors outside of the trigeminal and surgical measures to cut the sensory root are absolutely contraindicated. It is only by extremely careful sifting and separation of the cases in this way that failure to relieve the pain following reganglionic severance of the sensory root may be avoided. There is nothing that discredits a surgical procedure more quickly than its improper application. The operation is so certain to cure permanently if used only in the cases of major neuralgia that great caution must be exercised lest it be used haphazard for any painful condition referred to the nerve.

During the past four years, through the kindness of Dr. Charles H. Frazier, seventy-seven patients, in which a diagnosis of typical major trigeminal neuralgia had been made, have passed under my personal supervision. Of these, forty-one were males, thirty-six females. Sixty-one of these sufferers were over forty years old, forty-four of them had passed sixty. (See Table I.)

TABLE I: AGE INCIDENCE

Age of patients:	*Number of patients:*
20-30	7
31-40	10
41-50	9
51-60	16
61-70	27
71-80	6
80-+	2
Average age: 54.1 years.	77 total patients. (males 41, females 36.)

In thirty-five cases the right trigeminal tract was involved, in forty-two cases the left. The second and third divisions alone or in combination were most commonly involved (Table II.).

TABLE II.

	77

In fifty-one cases either the patients decided first to try the effect of alcoholic injection rather than operation, or we advised injection for diagnostic purposes in cases in which we had cause to doubt the certainty with which a diagnosis of major trigeminal neuralgia could be made. The technic of alcoholic injection of the various divisions, we have described elsewhere (1). In all seventy-seven injections were performed in these fifty-one cases. The third division was injected thirty-five times, the second division thirty-seven times and the first on five occasions. Alcoholic injection of the third division was successful in twenty-four cases, or 84.6 per cent. The second division injections proved for us more difficult, relief of pain being experienced in sixty-five per cent. of the attempts. The five injections of the first division proved effective. Out of seventy-seven injections of the three divisions, fifty-seven or seventy-five per cent., were attended with success. In twenty-five per cent. of cases, failure to hit the nerve involved and relief of the pain was recorded. There were no significant complications following injection with alcohol. In the four cases in which, judging from the extent of the anesthesia produced, the alcohol passed from the third division up into the ganglion no case of keratitis resulted. In eleven cases, eight following third, and three following second division injection, a herpetic eruption in the distribution of the nerve involved was noted for a day or two. In a single case of second division injection an external rectus paresis appeared, but cleared up within two weeks. Following the first alcohol injection the average relief of pain was fourteen months. Three patients have been pain free for over two years. On the average, subsequent to a second injection, the pain was checked for a period of eight and one half months; after a third injection, for five months.

Sufferers from trigeminal neuralgia who come to

us for advice are told that there are only two methods of treatment—injections of absolute alcohol into the divisions of the nerve, or avulsion of the sensory root. They are told that the injections are painful, usually, but not always successful, and transient in their effect. It is explained to them that operation and avulsion of the sensory root permanently relieves the pain, involves the administration of a general anesthesia, is somewhat more dangerous and in about ten per cent. of cases is followed by trophic keratitis in the eye of the side involved. Nearly all patients decide to have an injection at first. We approve of this for two reasons; first, because if successful in relieving the pain, operation later is certain to cure, and secondly, the patient becomes accustomed to the numb sensation in the face and will not complain of paresthesias following section of the root. It is not uncommon for us to perform as many as three injections in a period of about twenty-four months upon the same patient before the recurring attacks of pain bring it home that the alcohol injections are only palliative. After three recurrences the sufferers return with their hope for spontaneous recovery shattered and their morale broken, realizing that for unfailing relief we must resort to operation and begging for immediate surgical interference.

Since Spiller suggested that section of the sensory root behind the ganglion was the operative procedure of choice in the treatment of trifacial neuralgia, two refinements in technic, both suggested by Frazier, have appeared. The first of these is the preservation of the motor root of the trigeminus. As a result atrophy of the temporal muscle which may produce a bad cosmetic effect is avoided. On opening the mouth the jaw drops in the midline and does not deviate to one side. Secondly, in view of the incidence of corneal complications, in cases in which the pain has been referred to the second and third divisions only, he advises that the inner and upper fasciculus of the sensory root be left intact as this sends fibres to the first division which nourishes the cornea. In this way the nerve supply of the cornea is not wholly ablated and trophic keratitis is prevented. While it is not always possible to carry out these two steps an attempt should always be made to do so. A good exposure of the root and a little care in avulsing it fibre by fibre rather than piecemeal has shown that both structures may easily be avoided and left in situ. The motor root lies behind the sensory and is a separate and distinct bundle of fibres. The use of an electrode and observation of the result of stimulation of this fibre on the muscles it supplies, enables us to identify it beyond peradventure. In those subjects in whom the motor root has been preserved we have never seen any difference in the usual total anesthesia of the face which is customary after the complete removal of both roots. Apparently the motor root is purely motor and carries no sensory fibres.

It is not only in the relief of pain from major trigeminal neuralgia that alcoholic injections into the branches of this nerve or avulsion of its sensory root are useful. In malignant conditions of the jaws, cheeks and tongue which by involvement of the fifth nerve fibres at times cause severe, constant pain, relief may be obtained through blocking these fibres by one of the methods described. Our results with these cases will shortly be published.

In a series of twenty-six cases operated in for relief of trigeminal neuralgia the sensory root was severed behind the ganglion in all but two instances. There were no deaths in this series. Both roots were removed in thirteen instances, all but five cases being operated upon before we were attempting to preserve the motor root. In eleven more recent procedures the motor root was successfully preserved and in five of these the inner fasciculus of the root was left behind. In two cases intracranial neurectomy of the second and third divisions was carried out and the ganglion injected at sight with absolute alcohol. Both of these patients were elderly, sixty-eight and seventy-two years of age respectively, one showed glycosuria, and were poor operative risks. It is an easier, more rapid, and apparently almost as effectual a procedure to cut the nerves and inject the ganglion as it is to avulse the root. The relief from pain is not permanent as when the root is avulsed, but if the expectation of life is not long, and the subject in poor condition, the quickest operation which is at the same time adequate is preferable. We have used local anesthesia five times for this procedure, injecting the ganglion with a two per cent. solution of novocaine before manipulating it. The use of local anesthesia does not lend itself particularly well to careful dissection of the motor root and inner fasciculus. A heavy dose of morphine and scopolamine plus local anesthesia and then the administration of ether after the middle meningeal artery has been secured is the most satisfactory combination. In our last eight cases in which we avulsed the sensory root each patient received less than three ounces of ether. Once the root is cut the anesthesia is stopped for the operative field is within the distribution of the fifth nerve.

Twenty-four of the twenty-six patients obtained immediate and complete relief from their suffering. In two instances although the peripheral anesthesia was complete burning pain of a different type from that for which relief was sought and a sense of formication in the anesthetic area were noted. These two patients felt that they were but little improved by the operation. One of them had been apparently completely relieved by alcohol injection of the second division before operation. Too great care cannot be exercised in deciding upon radical treatment. Any atypical feature must be investigated and given scrupulous consideration. Even after experience with these borderline cases the pleadings of the sufferer for relief may lead to unwise surgical decisions.

The most serious common postoperative complication is trophic keratitis. In eight of these twenty-six cases this disturbance occurred. Three healed promptly in twelve hours on closure of the eyelid with courtplaster and did not reappear. Rapid healing of the keratitis following lid closure usually occurs. Six corneas remained ulcerated for forty-eight hours after temporary closure of the lids so that the eyelids were sutured. The ulcer healed and disappeared after the eye had been kept shut for two weeks. Another required four months of closure while the remaining case has the lid still

sutured eight months after avulsion of the root. None of those cases in which the inner and upper fasciculus of the root was saved showed any corneal complications. In any event whether or not corneal complications appear the patient should wear a protective goggle over the eye involved for six months. He should be told that the cornea is insensitive, that no irritant applications should ever be used on it under any consideration and that he should bathe it morning and evening with a warm boric acid solution for at least a year following operation. Two cases of transient paralysis of the frontalis muscle were noted, due probably to pull in the lower angle of the incision on the upper branch of the facial nerve. One patient had complete seventh nerve paralysis of the central type following avulsion of the root. This condition is slowly recovering. The most serious complication we have encountered was a case of external rectus paralysis. In an early case complicated by bleeding, in which speed was essential due to the patient's condition, the abducens nerve was avulsed with the sensory root of the trigeminus. This was due solely and simply to bad surgical technic and should not be held against the method of operation. It merely emphasizes the fact that this is a procedure which should only be carried out by those who have had wide experience with it.

There is a no more grateful class of patients to deal with than those who have been relieved from the torture of trigeminal neuralgia. Even those who have had to have the eyelids sutured—and if this is done skilfully, binocular vision is still possible—have expressed a willingness even to lose the eye if we can assure them that the pain has been relieved permanently. Freedom from pain and the dread of another paroxysm means everything to them. And this we guarantee absolutely that once the sensory root is severed behind the Gasserian ganglion all chance of a recurrence of their agony is gone.

SUMMARY

Trigeminal neuralgia is a condition of later life. The pain is epileptiform, lancinating and referred to the surface of the skin and mucous membrane supplied by the peripheral branches of the trigeminal nerve. The pain spasms follow a course parallel to the lower jaw and never run across the pathways of the three main trunks of the nerve. The second and third divisions are most commonly involved.

Injection of alcohol into the division involved or severing the sensory root behind the Gasserian ganglion is the only effective treatment.

Seventy-seven injections were performed on fifty-one patients with successful results in seventy-five per cent. of cases. The average period of relief following the first injection was fourteen months.

Twenty-six cases requested permanent relief through operative measures. Twenty-four were rendered completely pain-free. Two cases while the anesthesia over the trigeminal area is complete still complain of pain. Operation in these cases was a mistake as the patients were not suffering from true tic douloureux.

There were no operative deaths in this series.

Accidentally Removed Nasal Mucous Membrane Adheres and Functions When Replaced

ERNEST V. HUBBARD, M.D.,
New York

The following case is reported as one with an unusual outcome.

Case.—The patient was a male, clerk, thirty years of age, with a negative history, except for obstructed nasal breathing. On examination, a large spur on the septum was found, lying low on the right side. In view of a moderate resulting catarrh and slight tinnitus in both ears, the removal of the spur was recommended—apparently a simple operation under novocaine anesthesia. The mucous membrane was found adherent to the underlying cartilage and bone comprising the septum.

When the separation of the mucous membrane had been completed and the cartilage was removed, by accident the entire quadrangle of mucous membrane was torn away and removed also. This square piece, rather more than a centimetre on each edge, was undamaged except for a point where it was torn loose posteriorly. It was immediately placed in warm saline solution. The removal of the hard parts having been completed, an attempt was made to replace the curtain of mucous membrane unfortunately removed. Being lightly dried with gauze, the piece was set as nearly as possible in its original position. A Bernays sponge was introduced, followed by a second one. This plug was immediately moistened with saline solution, and, as it expanded, held the loose piece of mucous membrane in position. To my surprise, the next day when the sponges were gently removed, the replaced mucous membrane had adhered to its original position, its inner surface apparently fast to the inner surface of the mucous membrane unhurt on the opposite side. There was no hemorrhage.

The patient was seen daily for a week, the membrane remaining in place and having a good color. At the end of a month, the membrane continued to look normal and appeared to be functioning.

The effort to replace the membrane was made because of the large denuded area, fearing a subsequent atrophic rhinitis and ozena. That it was successful may suggest similar procedures in cases of a similar accident.

50 East Sixty-third Street.

Home Postgraduate Work by Means of Postmortem Examinations*

W. W. WAITE, M.D.
El Paso, Texas

One of the slogans which came out in 1892, at the time of the Columbian Exposition, went something like this: "All roads lead to the World's Fair." There should be a similar slogan in medicine, which should read: "All roads in medicine lead to, or emanate from, the postmortem table."

We call ourselves clinical pathologists and have really come to neglect the study of pathology itself. Strictly speaking, we are not as much clinical pathologists as are the internists, for the word "clinical" means bedside, so it is hard to see how an internist can escape from being a clinical pathologist.

The science of medicine is like all other sciences—if a man devotes all of his time to the study of one part, he becomes more or less lopsided and unable to draw reasonable conclusions from the facts presented before him. So, if we expect to serve the one particular field of pathology, we need to know some clinical medicine. If the clinician desires to serve his field well, he must know some pathology. A common meeting ground, where the various facts can be exchanged regarding all branches of the work, is at the postmortem table. The pathologist, by meeting with the clinician and occasionally seeing the patient, has a chance to keep his clinical knowledge in a serviceable state; likewise, the clinician can gain enough pathology by associating with the pathologist and following his cases at the postmortem table, to make pathology of some service to him. But how to bring about this condition in private practice is the problem that confronts us. Just who shall take the lead in carrying out such a program is a little difficult to determine, but it seems that so long as the pathologist is interested in pathology, he should be the one to undertake to organize and carry out such a program. If the pathologist only does such postmortem examination that he is asked to do that come from private practice, he will not do very many. Speaking from personal experience, the number thus obtained is not sufficient to keep one's knowledge of pathology in a real usable condition.

The clinician does a great deal of work in the free clinics in order that he may have cases upon which to study and experiment, but for the pathologist there is no such field. If we could afford to give a year or more of time when we served as interns to the acquiring of some experience in pathology, we might be able to continue to devote some time to it in the years when we are engaged in active practice. It is true that this is not a field in which to look for a large financial return at present, but it is a very good field in which to continue our education. It has been my experience that in private practice when some very unusual case ended fatally, the physician in charge was usually able to obtain a postmortem examination, but under such circumstances, unless the pathologist is up to date (and he can only keep so by doing postmortems), a good deal of information the case contained could easily be missed.

*Read before the Texas State Pathological Society, San Antonio, Texas, April 28, 1924.

It is the general custom now for nearly all bodies to be embalmed, and to do this, undertaking parlors have to be equipped with good operating rooms, and these same operating rooms furnish a convenient place for doing postmortems. If a way could be found of getting more postmortems, especially from private practice cases, material would be available for carrying on a system of study as suggested above. This idea was advocated in a paper read before the Texas State Association last year when it was suggested that a group of physicians with a pathologist could be organized for this purpose, and an attempt was made to put this idea into effect.

We have, in our community, several physicians who at various times have expressed a desire to have some sort of an institution by which more intensive study might be carried on than was being done. Some of these men were approached with the idea of organizing a group for the purpose of getting postmortems of the patients who died and use the material for study. Those approached were all deeply interested and agreed to try the plan, so an organization was formed consisting of about a dozen members. A group of this size is about as large as can work around a body and see what is going on and it is also about as large a group as can meet together for close study. When the work was started, we felt that if we could get fifty posts in a year that the work could be classed as a great success. We really did not get under way until September but up to the present time we have done approximately one hundred postmortems, and most of these have been done in the last six months.

In the organization of the group, no definite iron-clad rules were made, and the plan has been to have it just as free as possible. No officers have been elected. The pathologist acts as director and the others help in any way that they can. One collects the dues and pays the bills; another looks after the instruments; another takes the responsibility of notifying the men when there is to be an examination, and so on. There is a time agreed upon for regular meetings to review the material, and the postmortems in general are arranged at some convenient hour. As it is often necessary to hurry at that time, only brief histories are given but at the regular meetings, a more detailed history is given of the important cases, the literature is reviewed on the case under discussion, and every detail is brought out, including diagnosis and treatment.

A projecting outfit has also been secured and slides of the important lesions are projected on the screen. This is much more satisfactory than trying to demonstrate with a microscope, as that is time consuming and unless the person conducting the work looks at the microscope quite frequently to see that the slide has not moved, he does not know what is in the field, and one man may see one thing and another man something else. The members are greatly interested in the microscopic preparations as projected on the screen and seem to get a great deal from this fea-

ture. There has been fine cooperation among the members and they have helped the pathologist in every way possible. As soon as they became accustomed to the work various men were taught the technic of doing a postmortem, and now any one of them can do very well by himself if necessary. By getting into the work and actually doing it one sees a great deal more than he otherwise would and he also learns to observe for himself. This I believe is of great value to any one who is trying to do good medical work.

The cases examined so far have been greatly varied in character and of unusual interest. Taken as a whole, the material is far better than any I had a chance to see in hospitals. The examinations for the most part are done at the undertaker's rooms and the undertakers have been very courteous and helpful. Occasionally we have done a postmortem in a private home, but this is difficult and, at times, disagreeable.

The best specimens are saved and a museum has been started, and as the material accumulates, we hope to have something of real value to the community. Many of the specimens so far accumulated have been used to good advantage at the county society meetings. When a sufficient amount of material has been accumulated and classified, it will be useful to illustrate any sort of paper that one may wish to read before the society.

In reading books and journals we study about medicine, but when one follows his own clinical cases, he is studying real medicine, and there is no better way to study medicine than for a man to keep good records of his cases and when the patients die to follow with a postmortem. In our regular meetings, the discussion has been very free and open and to the point. At times, good work has been commended; at other times, weak spots in histories have been developed, and it has been shown why it is necessary that careful and accurate records be kept. This in turn brings out the fact that to make such records, one must learn to observe carefully and correctly.

As to the manner of getting postmortems, if one is interested in the work and asks with the hope of getting something, he usually gets it. Just how the men succeed in getting permissions, I do not know, but nearly all of them meet with great success, and I believe it is simply a matter of taking people into your confidence and telling them what you want. One of the members who has been somewhat timid in asking permission for the making of postmortem examinations was once told by the family after the funeral of one of his patients, that they were sorry an examination had not been made, and the doctor felt deeply humiliated that he had not asked permission for such examination.

From the amount of material we have had to work with, it is evident that it is our own fault if we do not get the opportunity to do more postmortems, for if we make an effort we can have all the material we can use.

We have kept records of our cases but they are not as complete as we would like to have them. Many of the cases have been worked up microscopically, but with so much material at hand, it is impossible to work it all over in detail. The work is still very new; as we get it organized better, and as the various members learn to help more, we believe that much better and more useful work can be done. While it takes a good deal of time and energy, it is well worth our while, and I do not hesitate to recommend it to anyone who cares really to study medicine. If the clinicians follow their cases in this way, they cannot fail to become better diagnosticians, and it goes without saying that the pathologists cannot fail to become better pathologists by thus cooperating with the clinicians.

Otitic Pyemia Without Sinus Thrombosis

J. COLEMAN SCAL, M.D.
New York

Otitic pyemia usually starts with the entrance of infection by way of the lymph vessels. It may also originate by direct infection either through a dehiscence or necrosis of the tympanic floor. In this case the pyemia evidently followed an acute otitis media, which terminated in a mastoiditis. The subsequent clinical picture and complications were that of sinus thrombosis, without organisms in the blood.

CASE.—J. F., aged sixteen, cigar maker, was admitted to Gouverneur Hospital, November 14, 1923. The diagnosis was acute mastoiditis. Previous history was negative except that there had been some ear condition five years previously, when the right ear drum was incised. The present history dated back to a few days prior to admission, when he commenced to have pain in the right ear. This was followed by a discharge of pus. The pain in this ear increased, the discharge lessened, and he then commenced to have severe pain from behind the ear to the top of the head. He was seen at the clinic and immediately referred to the hospital for a mastoid operation.

Physical examination upon admittance showed a boy apparently acutely ill. His face was flushed, the temperature was 104°, pulse 130, respiration 26. Examination of the right ear showed a marked bulging drum with a small anterior perforation present. There was a scant purulent discharge and a marked sagging of the canal roof. The mastoid process was swollen and slightly edematous, with the ear lobe pushed somewhat forward. Pressure on the mastoid elicited pain over the cortex, but not at the mastoid tip. Eyes, nose and throat were negative. The neck showed palpable submaxillary nodes. The chest was negative. The spleen was enlarged and palpable about two fingers below the rib margin.

A blood count taken November 15th showed leu-

cocytes 23,000, polynuclears ninety-one per cent. and lymphocytes nine per cent. The urine was negative. A bacteriological examination of the pus from the right ear showed the presence of the pneumococcus and staphylococcus albus.

On November 15th, a simple mastoidectomy was performed in the usual way, and revealed the cortex perforated in two places. The mastoid cells were found broken down to the tip. Considerable foul smelling, cheesy, necrotic material was removed. All diseased bone was excavated. The antrum was located and the lateral sinus exposed down to the bulb, which was found to be of a normal color and pulsating. The mastoid cavity was packed in the usual way, and the patient returned to the ward. The temperature dropped to 100.5°, but the following day the patient had a chill, followed by profuse sweating. The pulse was 120, and the temperature was 103°. He complained of severe headache and felt cold. A blood culture was negative. Urine examination was negative. The temperature remained high for the next two days, averaging 103°. On November 17th, the patient had another chill, and complained of severe headache and restlessness.

In view of the symptoms resembling that of sinus thrombosis, without positive blood culture, the patient was returned to the operating table. On November 20th the mastoid cavity was reopened, and the sinus inspected. The sinus was opened, and profuse bleeding resulted. The jugular vein was dissected out, the incision extending about an inch from the tip of the mastoid to the insertion of the sternocleidomastoid muscle. The vein was not resected, but was tied at both ends. The temperature commenced to fluctuate from normal to 105°, with a correspondingly increased pulse rate. Chills occurred at two or three day intervals. Repeated blood cultures taken on November 17th, 19th, 21st and 25th were negative. A lumbar puncture was negative.

The urine was found to be normal, with the exception of traces of albumin when the temperature was high. The blood counts showed a leucocytosis the highest count being 23,000, the differential count showing an average of eighty-two per cent. polymorphonuclears. No malarial organisms were found.

The high temperature and chills continued. On November 25th, the patient commenced to cough, and had some pain in the submaxillary region of the neck as well as in the chest. A sputum examination for tubercle bacilli was negative. X rays of the chest revealed nothing. The mastoid cavity was dressed in the usual way. Another blood culture was negative. The pain on the right side of the neck increased, and an abscess formed below the mastoid process.

On December 7th, the abscess in the neck was incised, and a large quantity of pus was evacuated. Pressure on the abscess cavity revealed the appearance of pus in the mastoid tip, behind the sinus. The entire mastoid tip was removed, and the cells around the sinus curetted away. The sinus was accidentally opened—free bleeding resulting. The sinus bleeding was checked and the abscess cavity packed and drained. No improvement followed. The patient began to expectorate mucopurulent sputum. X rays of the chest on November 30th showed a general peribronchial bronchiectasis, and on December 11th, a beginning consolidation of the right base, with the diaphragm obliterated, and a possible cavity in the left base.

In view of the clinical as well as the x ray findings, a diagnosis of empyaemia of the right side was made, and on December 12th a rib resection was performed under local anesthesia. About two inches of rib were resected and when the pleura was opened, a large quantity of foul smelling pus was evacuated.

The high temperature and chills continued, and on December 15th a swelling appeared on the neck near the thyroid. The following day this was incised and pus evacuated. On December 24th an area of swelling and induration appeared at the centre of the left thigh. This cleared up with wet dressings.

On December 26th, ten c.c. of staphylococcus vaccine were given intravenously, the patient reacting with a rising temperature of almost 105° and a severe chill. Another injection of vaccine was given on December 28th, and on the following day he commenced to feel better. The temperature commenced to subside. On December 30th the patient was feeling more comfortable. Two doses of staphylococcus vaccine were given on January 4th and 8th, 1924. On January 8th a small abscess appeared at the right side of the neck. This was incised and the pus evacuated.

The patient at this time was weak, and complained of pain at the back of the head. He seemed to be losing ground, and a blood transfusion was decided upon. The donor was his brother, from whom 300 c.c. of blood were obtained, and transfused into the median basilic vein. No reaction resulted. Injections of staphylococcus vaccine were continued.

The patient commenced to feel better, was more cheerful, and was taking a turn for the better, when at his parents' request he was removed from Gouverneur Hospital on January 15th and was admitted to the Manhattan Eye and Ear Infirmary the same day. The diagnosis on admittance was abscess at the nape of the neck. The temperature at the time of admittance was 101.5°. The next day, January 16th, the abscess was operated upon, a crucial incision being made over the occiput. Pus was found under the periosteum. The bone was found denuded. The temperature continued to fluctuate from 101° to 105°, but finally reached 99.5° on January 21st. About four hypodermic injections of insulin were administered. A Wassermann was negative. The blood count taken January 19th showed white blood cells 17,000, polymorphonuclears, eighty-two per cent., lymphocytes, twelve per cent. A blood culture taken January 17th showed no growth in twenty-four hours. Urinary examination was negative.

An x ray examination by Dr. Law showed the right mastoid noncellular, with the appearance of having been operated upon, which accounted for the absorption of bone. The thymus was not enlarged.

On January 28th the temperature dropped to normal. The patient gradually improved and was discharged from the hospital February 8, 1924. At this time the mastoid wound was completely healed.

The patient was seen several weeks later and appeared to be in good health.

COMMENT

In this case the occurrence of the embolic metastasis was undoubtedly due to the dissemination of septic emboli, such as occurs in otitic septic involvement of the sinus, yet at the several inspections of the sinus, no thrombosis was found. The blood cultures were always negative. In spite of this it was decided to ligate the jugular vein near the bulb to prevent the dissemination of septic material. The entire clinical picture was that of a sepsis with the characteristic temperature curve, chills, sweating, leucocytosis and high polymorphonuclear count. The metastasis to the various parts of the body was undoubtedly by way of the lymph channels.

It is our opinion that the sepsis was already present prior to the mastoidectomy, as the patient appeared quite sick when first seen at the clinic. The prognosis was very bad, but took a favorable turn after the blood transfusion, finally making a recovery.

44 West Seventy-fourth Street.

Bone in the Eye

PERCY DUNN, F.R.C.S.
London
Consulting Ophthalmic Surgeon, West London Hospital; late Lecturer on Ophthalmology, West London Post-Graduate College.

Scattered within the realm of human disease are problems in pathology of special and speculative interest, and undeniably among these is the formation of bones in an atrophied eyeball.

This change is not a pathological freak, occurring with a rarity suggestive of an exceptional environment, but one which for many years has been known, more or less exclusively, to ophthalmic surgeons as the natural sequence of degenerative processes. The presence of the bone and the source of its development have led many observers to investigate the problem. In regard to the broad outlines of the pathology there is a general agreement, but upon the question of detail much room exists for the expression of divergent views, views which still belong to the sphere of speculation. In this category is included the source of the osteoblasts which remains, among other details, a matter of uncertainty.

ATROPHY OF EYEBALL AND PHTHISIS BULBI

Incidentally an atrophied eyeball may be described as an eye which is soft, shrunken, and commonly flattened, following an attack of iridocystitis, such as may be caused by penetrating wounds or intraocular operations which have proved unsuccessful, by which the nutrition of the eye has been arrested by the inflammatory changes in the ciliary body.

It may be noted here that Fuchs draws a distinction between an atrophied eye, and one the condition of which is known, ophthalmologically, as "phthisis bulbi" (1). In his view phthisis bulbi, so called, implies destruction of the whole of the intraocular tissues, such as occurs after complete suppuration of the eye. In this case the eye contracts to the size of a hazel nut, whereas an atrophied eyeball retains some semblance to its original formation. Except for cosmetic reasons in the former case no interference is necessary; on the other hand, in the latter, in the course of time enucleation is expedient.

THE OSSIFICATION PROCESS

A period of years is required for the development of the ossification process in an atrophied eyeball—twelve years or more. Cases of much earlier dates have been recorded at which ossification has developed. But these are exceptional; nevertheless the possibility of their occurrence has to be borne in mind.

The mode of detecting the presence of the osseous plates is by means of palpation. Firm, backward pressure is needed, and this gives rise to tenderness, which is at once recognized by the patient. At the same time there may or may not be any sense of hard resistance of the surgeon's fingers, indicating the presence of bone. Again a patient may make no complaint of an eye in which bone has developed, until tenderness is revealed by palpation. The tenderness is probably due to the pressure of what remains of the ciliary body upon the hard bony substance. Palpation of slight degree is not to be relied on; it may elicit no sensation of tenderness, especially as the ossification usually begins at the back of the eye, first developing around the optic disc. The bone also is thickest in this situation, and in the bony plate there is commonly to be seen a round hole, masking the entrance of the optic nerve.

Upon reflection it is strange that bone, incidentally of the periosteal type, true bone with definite Haversian systems, should be evolved out of the degenerated inflammatory products of an eye in an atrophied state. This ossification has been defined as "the final stage of degeneration of the organized inflammatory products of plastic choroiditis" (Parsons). Possibly the eye occupying a confined and isolated space provides the conditions necessary for the development of the ossification process. That bone has been found in structures of the eye other than the choroid, such as the lens and retina, would seem to lend support to this possibility.

Whether the inflammatory changes in an eye, which are ultimately followed by the formation of bone, can give rise to an infective plastic nevitis in the other eye has not been established. No case of the kind has been proved. Modern observation must concede that socalled sympathetic ophthalmitis is not a "sympathetic" but an infective disease, and Hill Griffith has recorded that he has never met with bone in eyes removed for "sympathetic ophthalmitis." Furthermore, this disease is not known to follow

pus infections of an eyeball. Its infective origin must, therefore, depend upon some organism, still to be discovered, in common with other infective diseases, the microorganic source of which has so far defied the efforts of the bacteriologist to determine.

CASE REPORT

Appended are the notes of a case of bone in the eye which recently came under my observation.

CASE.—Mr. X, aged sixty-two, came on October 8, 1924. His previous history was one of many years of articular rheumatism, for which at intervals he had received treatment at Harrogate, Bath, Buxton, and other centres of hydrotherapeutics. Gradually he made a good recovery, and has now for some years been free from his former symptoms. Suddenly, about fifteen years ago, the vision in the right eye failed and blindness ensued. I was unable to gather from him the cause of this beyond the fact that he sought advice and followed the treatment recommended. Since then, at various intervals, his left eye has suffered from severe attacks of iritis. In the course of one of these the right eye became inflamed, and the symptoms suggested glaucoma. An iridectomy was performed by an ophthalmic surgeon. Subsequently the eye gradually became atrophic, and at the time of his visit to me it was shrunken, soft, and flattened. Such, I was told, had been its condition for approximately twelve years. No complaint was made of the shrunken globe; palpation at first revealed no response to tenderness, but when firm backward pressure was made a slight sensation of tenderness was admitted.

Examination of the left eye showed atrophic irritation of the lower lid. For some considerable time drops of a one per cent. atropine solution had been instilled daily in an attempt to dilate the pupil. But the iris was contracted and adherent throughout, the condition present being one of complete posterior synechiæ. The anterior capsule of the lens was fairly clear in the central pupillary space. The tension was good; ophthalmoscopic examination was not possible. The vision admitted was 6/nil; improved to 6/10 nearly, with Œ7 sph. Apart from the defective vision, the complaint made of the eye was an inability to face a bright light, occasionally lacrymation, and a sensation of discomfort. The last attack of iritis occurred four years ago; it persisted for six weeks. Since then the eye has been free from any recurrent reaction.

I enucleated the right eye on October 15th, Dr. S. H. C. Air being present and administering the anesthetic. A plate of bone was found in the eyeball. One or the other of the openings in the back part of the plate would indicate its position around the entrance of the optic nerve.

That these cases are of clinical importance will be inferred from the above, but added to this is their general pathological interest. Having regard thereto, the fact is somewhat strange that it should have escaped the notice of examiners in pathology. The subject suggests a question in an examination paper. For example: "Under what pathological conditions does bone develop in the eye? Describe the pathology of the process. Of what type is the bone? Discuss the views of the origin of the osteoblasts."

A Case of Obstetrical Paralysis

MAX STRUNSKY, M.D.

New York

The belief which is inherent and widespread among physicians as well as the laity, that practically nothing can be done for the chronic obstetrical paralytic, is the reason for reporting this case. This belief has become ingrown throughout the ages from the fact that those who have sustained this form of chronic birth injury have always remained permanently crippled. This empirical fact has, in recent years, been given a scientific background by the numerous and fine dissections which have been performed to ascertain the pathology of this condition by a host of observers, such as Duchenne, Stransky, Taylor, Lange, Thomas, Fairbank, Sharp, Sever, and others. These dissections have strengthened the belief in the incurability of this disease, for they showed that the ends of the torn nerves were usually found separated and were inherent and embedded in a cicatrix. Since regeneration of nerve is impossible through the medium of cicatrization, especially as it is known that a cicatrix grows more organized and more firm with time, the conclusion is therefore drawn that such a paralysis must remain permanent.

Any hope for the amelioration of this condition was destroyed when attempts to free the ends of the nerves from the adherent cicatrix and reunite them, as was done many times lately, failed to bring the much looked for results (1 and 2). However, since Dr. Sever, of Boston, has modified the Fairbank operation by myotomizing the contracted muscles and removing bony obstructions, his results in a large number of cases have been so encouraging that his procedure can be called the first of any vital importance that was ever done for this disease. The statistics of the Sever operation are found in orthopedic literature, but the report of a single case in a less specialized medium may bring it deservedly to the attention of a wider scope of readers.

CASE.—M. G., aged ten, had a typical obstetrical paralysis of the right arm. The conspicuous deformity in her case was a marked limitation of abduction of the arm. With the affected hand she was never able to touch the back of her head or to arrange her own hair. From birth she was conscientiously treated by many methods. The para-

lyzed muscles, the deltoid coracobrachialis and others, did not respond at all to the faradic current, and responded only sluggishly to the direct current, and gave a positive R. D.

OPERATION

Incision was made from the tip of the acromion down to the insertion of the pectoralis major. The latter muscle was cut across at its insertion. With the arm fully abducted and rotated outward, the subscapularis tendon was located and divided. Another incision was then made at the lower axilla, where many fibres of the serratus magnus were divided. The arm was put in a plaster of Paris cast in a position of extreme abduction for ten days. It was held in that position for three months by a brace, and passive and active motion of the arm was done daily.

FIG. 1.—Extreme height to which the patient was able to raise the right arm, before the operation.

RESULTS

She can now, without any effort, abduct the arm practically as high as the normal arm, though the scapula somewhat compensates for the movement. She can touch the back of her head, and do her own hair, and even throw the arm over her head and reach to the lower lobe of her left ear with her fingers.

It may be argued that the good results of the Sever operation in this case, prove only that the patient had a good deltoid, and that the only pathology was more of the nature of a disturbed muscle balance, probably a stretched paretic deltoid, overbalanced by stronger contracted antagonists, and that the Sever operation, by lengthening these contracted antagonists, removed the only obstacle which prevented abduction of the arm. For how, it will be asked, can the mere lengthening of mucles, which act physiologically as the depressors of the arm, also endow the arm with abduction power, when the main lifting power of the arm, the deltoid, is completely paralyzed?

The Sever operation does not pretend to add power, but only overcomes obstructions. I wish to emphasize this point especially, because it bears directly on the problem as to which case of obstetrical paralysis is suited for a Sever operation. In many cases, the antagonists of the deltoid may be contracted, but the deltoid itself is paralyzed. In such cases some surgeons may rule against the Sever operation, for the reason that it would be useless to lengthen the muscles which put the arm down, when the muscle which raises the arm is totally paralyzed. In practice, however, the Sever operation is indicated as long as the antagonists of the deltoid remain contracted, even if there is complete paralysis of the deltoid muscle.

The reason for this is twofold. First, in spite of all the tests we have at present to determine complete paralysis, such as extreme atrophy, positive R. D., absolute loss of voluntary power, etc., one cannot tell positively whether the nerves and cells supplying the muscle are completely degenerated, or whether there are some fibres or some live cells left somewhere, direct or compensatory, in the spinal cord, that innervate that muscle to some extent. The same is true as far as the muscle itself is concerned. It takes a section of the mucle in question to be viewed under the microscope to tell whether the muscle cells have all changed into connective tissue or fat. Also, we must not forget that all tests for complete muscle paralysis are made on a muscle which has been in a state of permanent hyperstretching during the entire life of the patient. The Sever operation, by freeing the muscle from the grip of permanent tension, augments the residual power, which is always present in paretic muscles. This, of course, may explain the improvement in the abduction power of the arm, which generally follows a Sever operation, where the deltoid is gone, or almost gone.

However, a more practical explanation for such an occurrence is found in a scholarly article by Dr. L. J. Pollack. He reports four cases of permanent paralysis of the circumflex nerve, which have learned in time to raise the arm. He quotes Bunts, who reported nineteen cases of circumflex paralysis, seven of which have recovered function, and of the seven, four recovered function in the absence of the deltoid muscle. He reviews also the literature of the subject, quoting innumerable writers who have reported similar cases. He experimented on the cadaver to learn the mechanism of such an occurrence (cutting away the bellies of the muscles around the shoulder, and attaching strings to the origin and insertion of the muscles, the ends of the strings operated by pullies), and he found that all muscles besides the deltoid, that are attached to the shoulder, and even those muscles that are the antagonists of the deltoid, have power to abduct the arm.

FIG. 2.—After the operation. Patient can raise the arm as high as the normal arm though the scapula compensates.

He says, in part, that the supplementary mobility in deltoid paralysis is produced probably by the subscapularis, the infraspinatus, the pectoralis major, and the supraspinatus, firmly fixing the head in the glenoid cavity. During this phase, external rotation of the humerus occurs. The serratus magnus, trapezius with the rhomboidei and elevator anguli scapulæ then produce a rotation of the scapula elevating the humerus. The abduction of the shoulder is then completed by the supraspinatus, coracobrachialis, long head of the biceps, serratus magnus, trapezius, rhomboidei, elevator anguli scapula, pectoralis major, and supraspinatus. The combined action of these muscles elevates the arm to an angle of about 65°. The movement of abduction of the arm backwards seems to be uncompensated, so that the movement necessary for

putting the arm in the hip pocket, in permanent paralysis of the deltoid, is impossible.

The muscles, therefore, which act primarily as the depressors of the arm, when their action is from their insertion, also possess the reverse power of elevating the arm. In obstetrical paralysis, these muscles are hypercontracted. They prevent abduction of the shoulder. The Sever operation, which cuts these muscles, and the extreme abduction of the arm, aided by a brace for about three months in order to prevent recontraction, make these muscles longer, and not only removes the barrier to direct abduction of the arm, but the power which they possess to raise the arms comes back. Though this form of abduction of the arm, which is executed by the depressors of the arm, is but a compensatory movement, and unnecessary to the normal individual, it is of utmost importance to the paralytic, because it is the only power left to him for raising the arm.

The operation should be done on much younger children than it is generally done at present, for the obvious reason that the obstruction to movement is only muscular at the beginning, while later, however, there occurs contraction of the capsule and the bones deform. It would obviate the necessity of having to chisel away the acromion process, which, in older children, is often found hooked down over the humerus, and which interferes with the raising of the arm. Or, as in the above case, for instance, the capsular ligament was already so contracted that when the arm was forced in abduction, it prevented that movement to the full. Since in this country we are going away from the Fairbank operation (opening the capsule) nothing could be done to overcome that part of the obstruction, except a thorough stretching. The result is that though the patient can abduct the arm as high with the affected side as with the normal, the movement on the affected side is compensated by the scapula.

Report of a Case of Spontaneous Pneumothorax in a Young Boy

HARRY APFEL, M.D.

Brooklyn, N. Y.

Case.—Male, aged sixteen. His mother was living and well. Father had had leg amputated for gangrene of the foot. Two brothers and three sisters were living and well.

The patient had had measles at the age of three. No other illness could be remembered either by the patient or by the family, but on close questioning it developed that the patient had suffered from a cough, which would come on occasionally, but no history of loss of weight, night sweats, or any expectoration, at any time, nor did the patient ever consult a physician for his cough.

The present illness commenced November 15, 1922. The boy, while busy with his routine work in the hardware store of his father, was seized with a rather sharp pain in his right chest. He walked upstairs to his room unassisted.

Four hours later I found him sitting on the edge of the bed, holding his hand to his right chest, his face bearing the expression of pain. He seemed to be a boy somewhat overgrown for his age. The head, eyes, ears, nose and throat were negative. There was a tendency to drooping shoulders and the chest was barrel shaped. The apex beat was visible and palpable in the fifth interspace and axillary line on the left side, and the right border under the sternum. This was verified by percussion and auscultation. No murmurs could be made out.

The right chest, on percussion, gave a tympanitic note throughout, both anteriorly and posteriorly. No breath sounds of any kind could be detected.

The left side gave normal percussion and auscultation, with normal respiratory murmur throughout (perhaps a trifle exaggerated.) The abdomen, genitals and extremities were negative. The respirations were short and catchy about 30 a minute. Pulse about 120 a minute, and temperature 100°. Systolic blood pressure 130, diastolic 80. Urine and blood were negative. The diagnosis was a right sided spontaneous pneumothorax.

The x ray examination of the patient's chest, taken a week after the onset of the illness, showed the following:

The intercostal spaces were much wider on the right side than on the left. There was marked illumination on the right side, indicating there was no lung tissue present in this area. In the hilum region (right) was a dense shadow, longitudinal, which was free from above and below. This was the former lung tissue which had collapsed. The left side showed the heart displaced to the extreme left and the trachea and pulmonary vessels also drawn over to the left side. The linear markings were greatly increased. This was due to the left lung functioning alone and increased pressure from the collapsing of the opposite lung. The costodiaphragmatic angle was free and clear. The left apex was also clear.

The patient was kept in bed against his wish. He was entirely free from any cough and discomfort. The pain had subsided after a single dose of morphine at the onset of the illness. There was no cough or dyspnea.

A second radiographic examination of the patient's chest on December 26th (about six weeks after the onset of illness) showed that the right lung had expanded again with the exception of the right extreme base and somewhat along the lower half of the axillary line. There was also a slight amount

of fluid at the right costodiaphragmatic angle. The extreme apex had not yet expanded. The heart had returned to its normal position.

REMARKS

Spontaneous pneumothorax is not as rare, nor does its occurrence always cause grave disturbance to the patient, as one would commonly believe. In fact, I recall a case (in the clinic of Professor Sargo, in the Wilhelmina Kranken Spital, Vienna, June, 1921) where the examination (including an x ray examination) of the chest disclosed a tuberculous cavity in the patient's left lung, the heart in its proper location. A therapeutic pneumothorax was recommended. Two days later, when the patient reported at the clinic, upon examination of the chest a spontaneous pneumothorax was discovered and although the patient's heart was found to be completely displaced into the right chest, there was no recollection on the part of the patient of having experienced any pain or discomfort at any time previous to, or since the last x ray examination of his chest.

Usually, however, spontaneous pneumothorax is ushered in by excruciating pain and a feeling of faintness and dyspnea, and not infrequently it is accompanied by shock, from which, however, the patient soon rallies.

This condition is rare in children and even among adolescents. It is more common in adults between twenty-five and thirty-five, and is likely to occur to people engaged in heavy occupations, where severe and sudden strain calling for extra severe exertion brings about a rupture of a long standing pulmonary and pleural lesion, usually of a tuberculous nature.

NOTES

S. West (1) has made experiments on lungs, postmortem, which have shown that unless the lung tissue has been previously diseased the alveola will stand a great deal of pressure, and will not rupture, and when the lung does rupture the result is usually an emphysema of the subpleural or mediastinal type and rarely intrapleural.

Ness and Allen (1) report a case in a healthy boy twenty-two years old who recovered within seven weeks, in whom no tuberculous symptoms could be found.

Hamman (2) cites a case where the patient suffered four attacks in the course of four years, and only after the last attack were tubercle bacilli found in the sputum.

Jachman (3) reports a case referred to his clinic for frequent pollutions and incidently only did the patient mention that he was experiencing slight pain in his chest for the past few days. On examination a complete right pneumothorax was found.

Morrison (4) reported a case in a boy of nineteen years with a recurrent attack in the left chest, five weeks after the first attack in the right chest, with ultimate recovery. Schoenstein (5) reported a case in a child eight months old.

Bourne (6) reported a case in an infant eighteen months old. On autopsy he found a left sided pneumothorax and left pleura studded with miliary tubercles. The lung on the same side showed a cavity at its apex and adherent to the pleura, and a right sided bronchopneumonia. Martin and Knox (7) reported a case in a boy of seven years following an outburst of crying, accompanied by vomiting, dyspnea, pain in the chest and abdomen; this was mistaken for acute appendicitis, but subsequently was diagnosed as pneumothorax.

Zuppinger (8) reported a case in a child two and a half years old; the pneumothorax came on while the child was asleep at night and proved fatal in thirty-six hours. The symptoms were severe abdominal pain, dyspnea, cyanosis of lips, cold perspiration of forehead, all of which came on suddenly in a child that was perfectly well, on retiring, in the evening. The autopsy showed a perforated lung due to a corn kernel which the child must have aspirated during its sleep (the mattress was full of these kernels).

Ash (9) reported a case of a four year old girl on the eleventh day following the aspiration of a little sharp stone. Rosenthal (10) reported the case of a sixteen year old boy following the ingestion of a sharp bone, which perforated the pleura through the wall of the esophagus.

Müller (11) reported a case in a sixteen year old girl where three round worms were found to have perforated the diaphragmatic pleura on the left side, and so caused a pneumothorax, which proved fatal.

Pitt and also Rolleston (12) each reported a case, both of which proved fatal within thirty-six hours. In both cases severe hemorrhages into the pleural cavity were found. Osler (13) quotes West to the fact that ninety per cent. are due to phthisis.

Pfoundler and Schlossman (14) give as the causes of pneumothorax the following: Phthisis, whooping cough, measles, bronchopneumonia, gangrene of the lung, softened bronchial glands and trauma, either from foreign body or of external injury.

One author, Goodhart (15), believes a rupture of an emphysematous bleb is the cause in many cases, which probably was the case with our patient, as far as one could judge from the existing evidence.

Latent Chronic Empyema*

MEYER A. RABINOWITZ, M.D.,
Brooklyn, N. Y.

Chronic empyema running a latent course without the history of an acute onset or a period of respiratory symptoms is an unusual occurrence. The following is a report of just such a case.

CASE.—J. J., female, single, fifty-three years old, was admitted to my service, May 9, 1921, at 5 p. m. This history as given by the patient and her friends was that she had been perfectly well and working until an hour before admission.

She was ashen gray, very dyspneic, pupils widely dilated, conjunctiva pale and without petechiæ. The veins of the neck were markedly engorged, the submaxillary glands were palpable. The tongue showed an angiomatous conditions of the veins at the base. The body was covered by a profuse clammy sweat. The aorta was not felt in the jugular notch. The lungs showed fine crepitant râles through the entire chest. Anteriorly over the right side, percussion revealed dullness from the third space merging into liver dullness and extending eight centimetres below the free border of the ribs. Posteriorly there was dullness merging into flatness as high as the fourth rib. No area of dullness could be made out near lower left dorsal spine.

The heart revealed a rough systolic murmur best heard at the apex, and transmitted over the whole heart into the left axilla. The right border of the heart could not be definitely made out by percussion as it merged with the dullness described in the right lower chest. The left border was made out fifteen cm. from the midsternal line in the fifth intercostal space. The pulse was regular, thin, and eighty to the minute. The blood pressure was 118 systolic, 60 diastolic. The liver was very tender, and felt eight cm. below the right lower ribs. There was no ascites. The spleen could not be felt. A slight edema was present. The patient showed no improvement and died forty hours after admission.

A diagnosis was made during life of an underlying arteriosclerosis involving the coronaries with secondary myocardial fibrosis. The immediate cause of death was thought to be an acute cardiac insufficiency, probably as a result of recent thrombosis of the coronary artery. However, just before the postmortem examination it was thought that the dullness of the liver upwards and downwards was entirely too great to be accounted for by an acute venous stasis, and that a massive effusion in the right lower chest was the more likely. On account of the absence of a Grocco triangle of dullness in the left posterior chest, it was suggested that a latent thickly encapsulated empyema could account for all the physical signs, that the heart sounds were too good for a severe myocardial necrosis resulting from coronary thrombosis. The dullness could be more readily explained on the basis of an effusion in the right lower chest pushing down the liver and forcing the heart over to the left.

The postmortem examination revealed the following: An encapsulated empyema on the right side. The pyogenic membrane above was at the level of the third intercostal space, below it extended down to the diaphragm, and was from one eighth to three sixteenths of an inch in thickness. It was dense and shaggy and enclosed a cavity containing about two litres of thick creamy pus having many fibrinous flakes. The right upper lobe of the lung was markedly congested, the right lower lobe completely collapsed, airless, tough and indurated, and densely adherent to the pyogenic membrane. The left upper lobe showed marked emphysema, the lower lobe was congested.

The heart was not displaced. The pericardium was normal. The right auricle and ventricle showed slight dilatation, the left auricle normal, the left ventricle not hypertrophied or dilated. The musculature of the heart throughout showed brown atrophy. The mitral valve was markedly sclerotic at the base of the posterior cusp. The other valves and coronaries were normal. The aorta was very elastic and showed a slight amount of sclerosis near the coronary orifices.

The liver was not enlarged, but pushed down. Its surface was smooth and pale. A pale dense hard area measuring one and one half by two and one half by one cm. was noted on the upper left lobe, which was probably an old cicatrized infarct. The liver was resistant to the knife, and on section showed a nutmeg appearance with fatty degeneration. The gallbladder and bile ducts were normal.

The stomach mucous membrane was pale. Multiple diverticula of the colon were present, none being very large or infected. The appendix was normal. The right kidney was enlarged and congested. The left kidney showed congestion and prominent renal arterioles. The spleen was slightly enlarged, firm and showed prominent Malpighian bodies.

The anatomical diagnosis was encapsulated empyema of right chest, fibroid pneumonitis of right lower lobe, brown atrophy of heart, slight aortic sclerosis, chronic passive congestion of the liver, spleen and kidneys.

A positive diagnosis could have been made during life either by the use of exploratory paracentesis or the use of the x ray. Either method was out of the question, because of the desperate condition of the patient, on account of the necessary exertion and added strain to the heart. Had a positive diagnosis been made, it would absolutely have come too late for surgical intervention. A mere thoracotomy and drainage would not have resulted in the obliteration of the tremendous cavity on account of its rigid walls and indurative fibrosis of the right lung. It is open to question whether the patient could have survived such a procedure at the time, or having survived the ordeal, been able to undergo an extensive thoracoplasty.

Practical Therapeutics

THE TREATMENT OF MALTA FEVER

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland

Although essentially an exotic disease, Malta fever is occasionally met with in temperate countries. Cases have even been reported in Switzerland. Therefore it is well to insist upon the tact that it *can* be met with anywhere.

Malta fever is an essentially proteiform infection, due to Micrococcus melitensis, discovered by Bruce. Its duration is long, the temperature chart usually showing a characteristic thermic curve composed of successive rises, often irregular and separated by periods of apyrexia. The undulatory type of fever is most common. Besides there are profuse sweating, constipation, neuralgia, rheumatoid pain, as well as many complications respecting no organ of the body. Emaciation is always prominent, the loss of weight amounting to from thirty to sixty pounds.

There are two other forms of the disease, although less commonly encountered, namely, the malignant type, characterized by an early typhoid state resulting in death in two or three weeks, and the intermittent type lasting for months and offering less severe complications than the other two varieties. Convalescence is invariably long.

Pathologically, there is no characteristic lesion. Those met with are the ordinary ones of septicemic processes, viz., localized areas of congestion in the gastrointestinal tract, sometimes hypertrophy of Peyer's patches and follicles, small ulcers exceptionally, moderate mesenteric adenitis, hepatic hypertrophy and congestion, spleen very large, hyperemia of kidneys, heart more or less flabby, foci of pulmonary congestion, etc. There is a mononucleosis and the specific bacterium can be isolated from the blood and viscera.

Propagation of the disease appears to be due to animals, especially goats. Transmission of the disease is due to inhaling microbiferous dust, or, more frequently, from ingestion of food carrying the specific organism—goat's milk or cheese and food soiled by the urine or feces of diseased animals or man.

In practice, one should invariably think of Malta fever when a patient presents an abnormal type of pyrexia; the differential diagnosis will be between typhoid fever, influenza, paludism, and pulmonary tuberculosis. The clinical signs are generally insufficient for making a sure diagnosis, hence blood examination is of the first necessity. Hemoculture and serodiagnosis will make the diagnosis a certainty.

The prognosis of Malta fever is relatively good *quoad vitam,* the mortality averaging about two per cent., but the duration of the disease—six weeks to one or two years—is the dark spot in the prognosis.

Prophylaxis consist of sterilizing goat's milk, but it must be remembered that there are other animals such as sheep, asses, mules, cats, and rats, that may be infected and infecting, thus contributing to the spread of the disease by soiling the various places where they live with their germ bearing urine. Hence the ways of contagion are multiple and therefore it happens that the etiological notion is rarely evident and in the majority of cases nothing can be found to explain the development of the disease.

As there is no really specific medication, the treatment of Malta fever is purely symptomatic, being directed to the fever and pain. Medium doses of quinine, pyramidon salicylate, aspirin or phenacetin, singly or in combination, may be essayed, always remembering that none of them affect the temperature and that if the fever is not high, as is usually the case, it is preferable to abstain from the exhibition of an antithermic medication which increases the already profuse sweating and has an unfortunate action on the digestic tract.

Should the thermic reaction be excessive, it is best dealt with by the exhibition of quinine in large doses *per os* or subcutaneously, but it must not be continued for too long a time. The neutral hydrochlorate of quinine, injected into the muscle in doses of two grams fifty centigrams at a single injection in the morning, and repeated again in the evening if necessary, is an excellent means for controlling the temperature. But above all, tepid baths, cold packs, and vinegar lotions, repeated as required, should always be resorted to.

Constipation should be relieved and the penetration of the bacteria into the intestinal mucosa will be prevented by repeated doses—thirty to forty grams—of castor oil and large irrigations of the bowel.

Analgesics for the relief of the painful phenomena are to be used with caution, and although not always successful, topical applications, *loco dolenti,* with suitable liniments should be tried.

For excessive sweating there is nothing better than atropine sulphate, in doses of one quarter of a milligram three times in twenty-four hours.

In the serious forms of the disease intravenous injections of electrargol should be given in order to activate the phenomena of organic defense, likewise physiological serum to sustain the organism and to facilitate the elimination of the bacteria and toxins by the urine.

Herzen and others are opposed to the use of Wright's serotherapy with the serum of immunized goats, as no positive results have so far been obtained, but they do advocate vaccinotherapy with injections of dead cultures of the Micrococcus melitensis, in doses of one quarter of a cubic centigram every ten days, but only in chronic cases with a low temperature.

The patient should invariably be kept in bed, and an absolute milk diet should be ordered at the onset of the disease, and this should be continued if the process assumes the more serious types. In the undulating type of temperature, broth, meat juice, and the yolk of eggs beaten up in broth or in milk, macaroni, etc., should be given. During apyretic periods a more substantial diet of eggs, jellies, light meats, creams, and jams is proper, and tonics con-

taining quinine, kola, and the phosphoglycerates are to be exhibited. The patient should wear flannel undergarments and avoid all chilling of the body.

When convalescence has begun a change of climate is essential, a high altitude being preferable, combined with ordinary medicinal treatment employed in any case of recovery from an infectious process.

Radium in Medicine.—C. J. Broeman (*Ohio State Medical Journal,* April 1, 1924) says that in all probability the most valuable influence of radium at present is to be noted in the amelioration or cure of conditions generally termed inoperable and incurable. One of the strongest arguments in favor of radium therapy is the fact that its rays show a selective action on different types of cells, and while all tissue cells are susceptible to its influence, the neoplastic, abnormal, or pathological cells are noticeably altered or destroyed, while the surrounding healthy cells resist the influence of these rays.

This selective action of radium is often lost sight of by the physician. Some are not willing even to admit this fact, but what better example can be given to illustrate this fact than the remarkable way a large cavernous nevus will disappear when radium is properly applied. In some cases not even a scar remains to show where the original abnormality was located. This result is not attained by any other form of radiation including the x ray, which to my mind proves that the rays given off by radium are, in some respects at least, entirely different in action from the x ray, which for instance does not materially influence nevi.

The author mentioned cases of splenomedullary leucemia in which he treated the patients with radium and they are living today, although not cured, and are well enough to continue their regular occupation. In these cases a large quantity of radium was applied directly over the spleen for from fifteen to twenty hours. One such application with 350 milligrams of radium an inch and a quarter distance, usually reduces the white cell count from 90,000 to 30,000. The spleen also becomes smaller with such an application. The following case which is given in detail is a typical illustration.

The author quotes the case of a man, aged twenty, who first consulted him on September 29, 1922. His chief complaint was inability to see well and do work as a clerk. He had previously consulted three physicians in as many states, without a definite diagnosis having been made. Examination showed a poorly developed boy, very pale. He talked rather foolishly, a condition which careful examination proved to be due to anemia of the brain. General physical examination, including the heart and lungs, was negative. Urine contained trace of albumin. Examination of the abdomen showed it to be greatly enlarged, resembling the potbelly of a child. The spleen practically filled the abdominal cavity, extending over on right side of lower border of the liver. Serological examination confirmed at three different laboratories, was negative. A diagnosis of splenomedullary leucemia was made. The patient was given two radium treatments with good results.

The author also calls attention to the fact that in generalized lymphosarcoma radium causes the individual nodules to disappear as well as the pain that is often associated with their presence. It is reasonable to assume that if the primary lesion in this disease can be treated thoroughly with radium in its beginning, this incurable disease may be prevented from its usual fatal ending. He also reports six cases of Hodgkin's disease in which five cases resulted favorably from treatment with radium, the outcome of the one case being unknown as the patient was lost sight of. The results obtained in Hodgkin's disease were all the more remarkable as a number of the patients were of advanced years. The author is of the opinion that no patient need die of Hodgkin's disease if the diagnosis is made before the entire glandular system has become involved, and radium properly applied in large enough quantities. He concludes as follows: It is urged that the value of radium be recognized as a powerful means of therapy, and its tremendous possibilities be given the attention it merits. The limits of its application are unbounded and it becomes our duty to further the practice of medicine with this splendid means in our possession, by exerting every effort toward the improvement of technic, applying our best powers of discrimination as to its application, and devoting the same diligent perseverance throughout, that has in the past been given to surgery and other forms of therapy.

The Use of Tryparsamide in Neurosyphilis.—W. F. Lorenz, A. S. Loevenhart, Thomas F. Reitz, and C. P. Eck (*American Journal of the Medical Sciences,* August, 1924) conclude as a result of their experience in the treatment of 185 cases of neurosyphilis over a two year period that tryparsamide and mercury salicylate are therapeutically effective in early paresis, meningovascular syphilis, and, to a lesser extent, in taboparesis, tabes and in advanced paresis. The beneficial clinical results generally precede the improvement in the serology. Definite paretic psychoses disappear as the result of treatment and the mental restoration has persisted over a two year period. Visual disturbances occurred in seven per cent. of the total number treated. In tabes and taboparesis twenty-three per cent. of the cases showed visual disturbance. Of thirteen cases showing amblyopia during tryparsamide therapy all but one cleared up after the withdrawal of the drug. Twelve of these cases were subsequently treated with tryparsamide without further eye disturbance.

Treatment of Tuberculosis with Sodium Morrhuate.—John Hume (*Lancet,* July 26, 1924) found sodium morrhuate of great help in advanced cases, but not so sucecssful in the early ones, in whom it appears to lead to a complete arrest of the disease. It is easily administered by subcutaneous injection. The author usually begins with 0.5 c.c., and if the reaction is only very slight, he proceeds to a dose of 1.0 c.c., administered twice weekly. There does not appear to be any advantage in using a larger dose. Sometimes a slight local reaction around the needle puncture is observed which is apt to occur if a month or so had elapsed since the last injection. It is used in a 3 per cent. solution. The bottle should be allowed to stand in warm water for a few minutes before use, when it should be quite clear.

The Treatment of Socalled Essential Arterial Hypertension*

LEWELLYS F. BARKER, M.D.
Baltimore, Md.

Slowly but surely our knowledge of the states in which chronic arterial hypertension is encountered is becoming more extensive, more precise, and better coordinated. Clinical workers and laboratory investigators are vying with one another in observation and experiment directed toward the unravelling of the very complex problems of vasomotor regulation in health and in disease. The number of publications that have appeared in recent years upon the subject of blood pressure is appalling, though an occasional collective review like that of H. Kahler (1) goes far toward lightening the burden of those who desire to keep pace with the progress of knowledge in this extraordinarily interesting and diligently tilled field. Thanks to studies at the bedside, we can now recognize a whole series of symptomatic hypertensions, for example, those associated with renal diseases, with arteriosclerosis, with cerebral lesions, and with plethora, and we distinguish also a group of hypertensions that, for the present, we speak of as primary or essential hypertensions (hyperpiesis) because of their occurrence in the absence of the conditions believed to be associated with the symptomatic forms. Physiologists, pathologists, pharmacologists and biochemists have, through animal experiment, provided us with a mass of information regarding possible modes of origin and the mechanisms of heightened blood pressure. And, recently, clinicians have made laudable attempts to evaluate this experimental work for the better understanding of the pathogenesis and for the more scientific classification of the hypertensions met with in man.

Such attempts at pathogenetic subdivision have been fruitful, not only for the groups of hypertensions of nephropathic and of atherosclerotic association, but also for the functional hypertensions that appear to be independent of organic lesions in the kidneys or in the heart and bloodvessels. Particularly noticeable of late have been the efforts made to distinguish hypertensions according to the part of the vasomotor regulatory apparatus upon which the stimuli that give rise to increased blood pressure impinge. And even though it may seem to some of us that discrimination between centrogenous and peripherogenous hypertensions, on the one hand, and between neurogenic and chemogenic hypertensions, on the other, is less easy (in the concrete cases met with in actual practice) than some nosologists would have us believe, still we should welcome warmly every such serious endeavor and should seek, through carefully controlled clinical experience, to determine the value of each newly proposed grouping.

For if, for the hypertensive states, we are ever to develop a therapy that is something more than mere symptomatic or empirical treatment, it is essential that we acquire exact knowledge, 1, of the internal and external causes that are operative in each form of hypertension; 2, of the effects that follow upon the causative influences, and 3, of the serial order in which those effects make their appearance. Rational therapy can make headway only as our knowledge of etiology and of pathogenesis progresses. In the interest of therapy, therefore, as well as of physiology and pathology, it is highly desirable that investigations of disturbances of the vasomotor regulatory apparatus continue to be prosecuted with unremitting vigor.

In the treatment of socalled essential hypertension we are still greatly handicapped both by our lack of knowledge of its causes and by our defective understanding of the serial sequence of events that constitute the links of its pathogenetic chain. That the causes lie partly in the germ plasm and partly in environmental influences seems certain. The tendency of essential hypertension to occur in families, as well as its incidence among persons of certain types of constitutional makeup (those with certain vasopathic, neuropathic and endocrinopathic inferiorities) point to a *predisposition* that is genotypically determined. Studies in constitution clinics should prove helpful here.

What the environmental factors are that influence persons thus predisposed, by acting on their vasomotor regulatory mechanisms so that disturbances occur that result in the appearance of chronic arterial hypertension, are far from being clear. They may, and probably do, vary in different cases. Among those that, according to our present knowledge, seem to be of greater or of less importance may be mentioned: 1, infectious processes; 2, chronic intoxica-

*Read by invitation before the New York County Medical Society, December 22, 1924.

tions; 3, dietetic errors, and 4, exposure to stresses and strains (mental or physical) that increase the wear and tear of life. Success in prophylaxis will depend upon a more precise formulation of these influences of heredity and of the environment than we as yet possess. But sometime, doubtless, physicians will reach a stage of knowledge upon which eugenic and euthenic programs that will prevent essential hypertension can be definitely and confidently proposed. Even now, the careful supervision of families by general practitioners, the early detection of symptoms that point to the existence of the predisposing constitutional inferiorities (O'Hare and Walker have called attention to some of them that occur as early as the second decade of life), and careful education in physical and mental hygiene, such as sensible diet; regularity of work, exercise, rest, recreation, bathing and sleep; maintenance of the body weight at or a little below the calculated ideal; proper care of the teeth and gums; regular habits promotive of the elimination of waste products from the body; avoidance of every kind of excess; the cultivation of self-control; and arrangements for a well balanced life with normal satisfaction of all the human desires and instincts, will do much to prevent the development of the disturbances of the vasomotor regulatory mechanism under discussion.

The application of causal therapy, once essential hypertension has been discovered to exist, up to now has had to be limited to education in hygienic living, to the reduction of weight in the obese, to the removal of discoverable foci of infection and sources of chronic intoxication, and to psychotherapy in the broader sense, upon which I have always, for the treatment of this disorder, laid considerable stress (2). It is the duty of a physician to allay the fears of the hypertensive patient and to inspire him with confidence and hope. After a thorough diagnostic study, including a careful investigation of physical, mental and social habits, of hours of work and rest, and of exposure to stresses and strains, the patient's exact situation should be explained to him, and definite assurance given that he will be instructed in the best way to live and to enjoy life despite his hypertension. A regimen, corresponding to the stage of the hypertensive process in which the physician finds him to be, should then be initiated, one that is calculated (according to the circumstances) to cure, to arrest, to delay, or to mitigate the disturbance of the blood pressure regulating mechanism. And this regimen should be closely supervised, at least until the patient has been taught how best to conduct his life in the interests of his health and of the continuance of his working capacity. A conscientious physician and a cooperative patient will not go unrecompensed for their trouble if they will pay careful attention to the details of treatment, especially in the early stages of essential hypertension. Occasionally the blood pressure will thus become normal and stay so. More often, the pressure can be markedly reduced and kept at a relatively low level over long periods.

In addition to the measures just discussed, patients not infrequently urge their physicians to make use of remedies intended to lower the blood pressure directly rather than to remove the influences believed to be causative. And many physicians yield to this desire for a socalled functional therapy. Some measures of this sort there are that can be applied probably without harm. Temporary rest in bed, a short vacation with injunctions against overexertion or excitement, a course of tepid baths with massage, or exposures to the high frequency current, or to radium emanation, may be followed by some temporary reduction of the pressure and will probably do no harm, except perhaps that such measures may sometimes mislead the patient a little as to the principal aims of therapy. As a rule it is best when the pressure is markedly elevated to discourage the idea of resorting to forms of therapy that are intended directly to reduce the blood pressure to the normal level or near it. The use of nitrites, particularly should be avoided (except in complicating angina pectoris or in hypertensive crises) since patients usually feel worse after their administration, even though the pressure is reduced by them. In emergencies, venesection or lumbar puncture may be used with advantage to bring about a pressure reduction. By restriction of the intake of sodium chloride to 0.5 gram a day Allen states that he has been able in many instances to reduce the blood pressure markedly and to hold it at a much lower level than is possible without salt restriction. Such a regimen is not without its hardships, however, and in some instances salt deprivation symptoms (asthenia, anorexia) add to these hardships. I have usually been content with a more moderate restriction of the salt intake. The possibility that some increase in the pressure is needed by the patient should not be lost sight of, though I hesitate to lay stress on an assumed compensatory nature of arterial hypertension because of my prejudice in general against the entertainment of teleological hypotheses.

Recently, a number of other methods have been vaunted for pressure reduction, among them intramuscular sulphur injections by Rusznyák (3), the intravenous injection of hypertonic glucose solution by E. Meyer (4), and systematic bromide therapy by Henius (5).

Thus in the medical clinic of v. Korányi at Budapest, Rusznyák injects one centigram of a one per cent. suspension of sulphur in olive oil into the gluteal muscles and at intervals of two or three days gives successive injections, increasing the doses to two, five or even ten centigrams, "until the spasm in the peripheral vessels is overcome and a marked fall in blood pressure occurs." After four or five days he gives a second course, and a month later more injections. Combined with rest in bed, reduction of the intake of salt and fluids, and veronal at night, he reports marked pressure reduction and improvement of subjective symptoms. He attributes the fall in pressure to the febrile reaction produced by the sulphur. He asserts that the pressure often stays at a lower level for a long time, perhaps because a vicious circle has been broken into. The treatment is admittedly painful.

In Meyer's clinic, in Göttingen, the use of intravenous injections of hypertonic solutions of glucose was begun for the relief of angina pectoris in hypertensive patients (according to the earlier suggestion of Büdinger in 1914). To Meyer's surprise not only was the angina relieved but the blood pressure remained lower, often for some time. He then tried

he same remedy in essential hypertension and secured marked pressure reductions, he believes with benefit to his patients. He injects ten c. c. of a wenty per cent. solution of glucose intravenously. The pressure is said to fall gradually after a time (thirty minutes to two or three hours) and may remain down for several days. Anginal attacks and attacks of intermittent claudication are said to vanish, even if the blood pressure subsequently returns to its former level! Since there is often a hyperglycemia in hypertensive states, Meyer suggests that the glucose injected may act (not because of increased glucose content of the blood) but by bringing about some dislocation of the system of blood colloids.

In Kraus's clinic in Berlin, Henius, because Kylin of Stockholm viewed essential hypertension as a general vasoconstriction of nervous origin, tried systematic bromide therapy (three or four doses a day) for two or three weeks at a time, repeating the course from time to time. Not only did the blood pressure in the patients treated remain at lower levels but certain symptoms (headache, precordial oppression, and fatigability) disappeared. He used the treatment on patients who could not afford to rest and states that they continued at their occupations while undergoing treatment. He believes that besides relieving symptoms a favorable influence is exerted upon the disease process itself.

The three methods of functional therapy mentioned have only recently come to my attention and I have not as yet had any personal experience with them. I merely mention them in order that any one who is interested may give them a trial, if he desires to do so. In connection with the bromide therapy, I may say that as a sedative in neurotic hypertensive patients I have been pleased with the effects of the compound chloral and bromide mixture of the National Formulary. It might, I think, be tried systematically in place of the simple bromide treatment of Henius. Kylin has recently suggested a combined calcium and bromide therapy, not uninteresting in view of Ralph Major's observations upon the prompt reduction of the increased blood pressure in methylguanidin intoxications by the administration of calcium.

One point in connection with the passing of judgment upon the effects of remedial measures in chronic arterial hypertension should, I think, be particularly stressed; I mean the great variations that the pressure may undergo independent of any treatment that we apply. The keeping of blood pressure curves, in essential hypertension especially, will convince any cautious observer of the importance of these socalled spontaneous variations.

In the later stages, and especially in the terminal stages, of essential hypertension, complications (cardiac, renal, cerebral) may become threatening. Here a sensible regulatory therapy, that is to say, a therapy directed toward helping the body to react against the disease process, may become necessary, viz., support of the heart; protection of the kidneys; promotion of elimination through the intestine and the skin. The general principles of such a regulatory therapy are so well understood and so generally applied that I need not stop to describe them. Digitalis should, in my opinion, be used in the failing heart of arterial hypertension just as in any other form of myocardial insufficiency.

It is not necessary for me to discuss the treatment of the single symptoms of which hypertensive patients may at times complain. Not that I consider symptomatic therapy unimportant; on the contrary, it should never be neglected by the physician, for, properly applied, it will add much to the comfort and welfare of the patient. Insomnia, headache, dizziness, apprehensiveness, anginoid pains, dyspnea, have their special significance and demand appropriate treatment for their relief. For insomnia, allonal is helpful; for headache, luminal in small doses; for angina, intravenous hypertonic glucose solution; and for dyspnea, digitalis.

Excellent discussions of the details of certain features of the treatment of essential hypertension will be found in recent articles (6, 7, 8, 9, 10, 11).

But none of us can be satisfied with the methods of treatment that are now available. New and better methods of treatment and especially of prevention must be found. There will be no short cut to these. They can only be elaborated after the confines of knowledge have been further extended in our experimental institutes and in our wards and clinical laboratories. Especially promising would seem to be the studies, 1, of the capillary circulation with its "peripheral heart," and 2, of metabolism, and especially of mineral metabolism, that are now being prosecuted. I have been particularly impressed by the great advances made in our knowledge of chemical influences upon the respiratory regulatory mechanism and especially of the relations of the hydrogen ion concentration of the blood and of the nervous tissues to the activity of the respiratory centre (12).

It has been very clearly shown there that the physiology of respiration falls in large part within the domain of the physiology of mineral metabolism, respiration serving as a most delicate regulator of the acid base equilibrium in the organism upon which the normal functions of the body tissues so largely depend. Now the main vasomotor centre that has to do with the regulation of the vasoconstrictor and vasodilator impulses throughout the body (and, accordingly, with the regulation of blood pressure) lies near the respiratory centre. We are, therefore, confronted by the task of determining for this latter centre the conditions by which it also is influenced. It may be long before we have such precise information regarding this vasomotor regulatory mechanism as we already possess regarding the respiratory regulatory mechanism.

Investigation of the blood serum in certain cases of nephropathic hypertensive states has, however, already shown the existence of marked deviation from the normal in the relative quantities of the several electrolytes and the electrolytes present (*poikilopikrie* of Straub). In such cases the kidneys seem to have lost the power promptly to excrete excesses of acid and basic valences corresponding to varying demands; according to the constancy of content of the serum in individual ions becomes impaired. But studies like those of Henderson, of MacNider, of Van Slyke and Cullen, of Allen and Sherrill, of Denis and Hobson, of Mosenthal and Short, of Wallace and Pellini, of Palmer, Atchley,

Loeb and Benedict in this country, of Marrack in England and of Straub and Meier in Germany are long and tedious. It is no easy matter by physical chemical methods accurately to determine anion and cation balances and dislocations or to make the other elaborate analyses and deductions that work on mineral metabolism and on colloidal chemistry entails. But those who are doing clinical investigation await eagerly the results of such researches and are hopeful that through them before very long more of the mysteries of essential hypertension may be unveiled.

The Importance of High Blood Pressure

LOUIS FAUGERES BISHOP, M.D., Sc.D., F.A.C.P.

New York

High blood pressure is a sign of some underlying disorder or autointoxication and is almost certainly a compensatory process. It is wrong to treat it simply by dilating the vessels or by depressing the action of the heart. Nitroglycerin is useful in any crisis that comes to a person with high blood pressure and everyone with high blood pressure should have it on hand to use if anything goes wrong. A temporary or momentary reduction of the pressure to relieve pain or prevent damage has nothing to do with the old fashioned attempt to reduce blood pressure by drugs or electricity. The essential thing to treat is the overeating, worry, and the neglect of exercise that are so often at the bottom of the underlying condition. The object of our treatment is not to reduce blood pressure but to prevent a further rise due to a continuation of the underlying cause. While it is only sensible to give a person coming to one in an excited stage of blood pressure disease a short period of rest in bed, nevertheless, physical immobility is the worst thing that can be inflicted upon a person with high blood pressure. I have witnessed the continuing good condition of some of the most extreme examples of high blood pressure disease that one ever encounters through insisting upon exercise out of doors every day to the point of physical fatigue. These exercises, which become a hobby, may take the form of golf or may be facilitated by visits to cure resorts, have not under my observation resulted in any of the predicted accidents due to ruptured bloodvessels or a dilated heart. Worry, of course, is the great foundation of blood pressure diseases and these persons should come under the moral as well as the physical care of the physician who should endeavor by all means to evolve a proper philosophy of life. This implies the curbing of unreasonable ambitions. As to drugs, a full dose of castor oil at least once a month is a life prolonging procedure.

When people come under my care in the excited stage of blood pressure disease showing every sign of toxemia it is my custom to prescribe castor oil according to the following formula: A full dose the first, third, fifth, twelfth, twenty-sixth, fort seventh and eighty-fifth day of treatment. Aft that it is to be continued every four weeks. Peo under observation for ten or fifteen years for hi blood pressure have spoken with confidence of t benefit they derive from their monthly dose of cast oil. As to nitrites, nitroglycerin seems to fulfill eve need and I seldom use the others.

Nitroglycerin regulation in a high blood press subject, particularly if he has angina, is not an ea matter. He is taught to experiment with a ve small dose of something less than a two hundre of a grain, and he is told to take one on all th occasions where it proves satisfactory. A single d will often break the nervous tension that keeps person awake at night and a single pellet will of relieve cardiac distress and allow the person to ta the exercise he needs.

After twenty-five years' trial electricity has prov to be a failure in producing any lasting benefit a I have seen it do a great deal of harm.

The use of digitalis in high blood pressure su jects is now recognized universally to be benefic Its continuous use is absolutely necessary in peo who show a tendency to recurrent attacks of sui cative edema.

Bromide is among the best systemic remedies high blood pressure. By putting the whole nerv system in flexible splints, by the use of five gra each of sodium potassium and ammonium bromi three times a day, one can often help a good d while the person is gaining his physical equilibri through exercise, diet and castor oil.

With regard to diet, I have been impressed by large number of people seriously ill of high bl pressure disease of the cardiorenal type who h been distinctly benefited by the withdrawal of e from the diet. In some the result has been so strik that I cannot but believe there was an anaphyla reaction from the eggs in the diet. Unfortunat it is not the universal rule. There are those w

very high blood pressure who tolerate eggs very well. When a man has taken eggs out of his diet, including the eggs in madeup dishes, he is exercising a supervision over his food that is quite comprehensive.

I have had my suspicions that the salt free diet often works as a means of reducing food intake on account of the elaborate attention necessary. In the same way an eggless diet reduces the intake of rich dishes and even where there is no specific sensitiveness to eggs, proves useful. I have seen extreme cardiovascular disease where the return to an egg diet had been repeatedly followed by very definite symptoms of general systemic irritation and where I felt morally certain that the eggs were specifically harmful.

No one would be foolish enough to say that high blood pressure is not a dangerous condition, but most of us have reached the conclusion that an unwise reduction of it is even more dangerous. In several instances people with blood pressure as high as 240 systolic and 120 diastolic have been followed for more than ten years while they took care of themselves by a suitable regimen. It is universally recognized now that a high diastolic pressure is more serious than a high systolic pressure. A high diastolic pressure usually indicates a granular kidney which of course is always threatening to result in one of the terminal accidents.

We must refer once more to the question of secondary low blood pressure. I tried to introduce into literature the term "secondary low blood pressure" in my first book on blood pressure but, like many other small enterprises that have been launched in literature, this term has never succeeded, apparently, because I have seldom seen it in use. By secondary low blood pressure I mean low blood pressure following a previously continuing high blood pressure and I pointed out how important it was to distinguish between the systemic low blood pressure that one encounters in so many neurasthenic subjects and the low blood pressure that was found in invalids who had previously had high blood pressure. The recognition of this condition in very sick people has often led to brilliant results. A good rule is to maintain, if possible, the usual pressure in every illness. This leads us to the matter of cerebral hemorrhage.

As a matter of fact a cerebral hemorrhage does not occur with any more frequency in very high blood pressure patients than in those whose blood pressure is not so high. The arteries of a high blood pressure subject have been trained through years of resistance to take care of this pressure and the chances of rupturing a small artery are not very great. In fact, cerebral accidents in cardiovascular renal disease often consist of thrombosis of the diseased artery in a person with moderate pressure and we must abandon the purely mechanical conception of this matter. When we come to the transient paralyses and aphasias that are quite common in this group we like to believe as much as we can that they are due to spasm of the artery. We are forced to confess, however, that some of them are really slight hemorrhages or a blocking of a degenerated artery.

Blood pressure in acute disease has received an undue amount of attention and low blood pressure has led to much unnecessary worry. As a matter of fact, in very sick people low blood pressure is a conservative matter and when it has been proved that there is no lack of response to an actual demand for higher blood pressure it need not be treated to raise it. In fact, a high blood pressure is often more of an indication of failing circulation than low blood pressure. The reaction against circulatory failure by contraction of peripheral vessels is often Nature's warning of impending heart failure.

In cardiac disease the blood pressure is dependent more upon complications than upon the heart, except in aortic regurgitation when we get low diastolic reading and a large pulse pressure. In mitral stenosis without complications the pressure is ordinarily low. When there are complications it may be much higher.

High blood pressure is a symptomless condition and is present in a great many people who are entirely unconscious of its presence. These people have high pressure because it is compensating for some disorder. There is a strong feeling on the part of many clinicians that the kidney is the most usual site of the disorder for which high blood pressure compensates.

A nosebleed often calls attention for the first time to high blood pressure though the bleeding itself is usually occasioned by some slight ulcer or other lesion in the nose. Such an example of high blood pressure has been under my care for ten years after the nose bleed had drawn attention to it for the first time when the mercury stood at 240.

That blood pressure is a compensatory matter has received consideration from a great many medical philosophers. The parallel idea that arteriosclerosis is compensatory and that the bloodvessels thicken to prevent dilatation in high blood pressure has not been considered so often. It would be easier to carry this conception if it was not confused with primary disease of the bloodvessels. Primary disease of the bloodvessels constitutes an entity separate from the usual group of cardiovascular diseases.

Apparently, high blood pressure compensates in two ways. In the first place it compensates in supplying blood to the tissues that need the extra supply, either on account of diseases of an organ or because of an extra demand for activity of the organ. When compensation is successful there are no symptoms. When a person with blood pressure without symptoms comes under observation we discover it by the sphygmomanometer and we can judge the duration of the disease by the amount of hypertrophy of the heart.

The importance of a strict regimen for people with high blood pressure is not so much to improve their health at the time, for that is often good enough, but to prolong life and prevent future illness. You cannot permanently reduce blood pressure. You can depress it for a long time but that does not mean that it is cured. What we wish to avoid is degeneration of the bloodvessels leading to apoplexy and degeneration of the kidneys leading to Bright's disease. This is accomplished by a regimen involving diet, out of door exercise and intestinal hygiene. An important measure is the monthly dose of castor oil. If an inactive person who has a high blood pressure from any cause whatsoever does not alter his mode of life his kidneys are being damaged by the elimination of toxins that will continue until his diet is

changed and he helps the kidneys to function better by out door exercise. Even when there is definite evidence of arterial degeneration a suitable regimen will carry a person with a blood pressure of 180 or thereabouts for many years. Even when there is evidence of arterial thickening, as shown by examination of the bloodvessels, exercise becomes even more important. We need not fear the accidents that are so much talked about. People do not drop dead very often from cerebral hemorrhage due to exercise. Thrombosis is equally imminent in cardiovascular disease, and even though a percentage of deaths from cerebral hemorrhage should, on more critical examination, prove to be somewhat increased by exercise, nevertheless it is quite certain that the accidents due to thrombosis would be so much diminished that the average life of a whole group would be vastly prolonged.

ETIOLOGY

High blood pressure is more often found in men than in women, though, probably, extremely high blood pressure occurs more frequently in women. This is only an impression and not founded upon actual count. Heart disease seems to be a man's disease, in a way. At least my experience in heart work for the past sixteen years has shown a numerical predominance of men as patients.

Heredity plays a high part in producing blood pressure and here we must consider the possibility of a syphilitic taint.

Primary disease of the bloodvessels often exists without high blood pressure and as noted above has little to do with the toxic nephritic group of average practice.

The origin of high blood pressure is so much related to kidney damage that we cannot separate the two in a great many instances. But there are numerous examples of high blood pressure in which there is no chemical evidence of kidney disease. Experience has shown, however, that later the chemical evidence of kidney disease did appear. This makes it seem probable that it had previously existed without chemical manifestation.

It seems to me that a diagnosis of nonrenal blood pressure would have to be founded upon an elaborate observation of renal function and would certainly require a determination of the nonprotein nitrogen in the blood.

The effect of tobacco upon arteriosclerosis is dependent upon the fact that there is a rise of pressure of short duration. This follows smoking and probably does not do any mechanical harm. Excessive smokers very often have low blood pressures. This may be accounted for by the fact that people with low blood pressure get great comfort from the temporary stimulation that comes from the slight rise of pressure due to each indulgence. In advanced arteriosclerosis a person develops a distaste for tobacco. At this time, for some reason, the physiological effect becomes disagreeable.

In speaking of high blood pressure the question always arises as to what is the normal pressure. The rule of adding one hundred to the age is very comforting to older people, but is not agreeable to fact. This rule probably is harmless up to the age of thirty, but after that half a degree a year is all that can be added without departing widely from the results of the very elaborate studies made by the life insurance companies, who after all are the people most definitely interested in averages and they are without the personal bias of the physician who has to deal with the feelings of his patient. Wide experience and discussion have shown that in most instances the method used by applying measured pressure in the brachial artery gives a correct estimate in blood pressure. It is an important point not to take the findings of a single examination as being necessarily correct. It is shown, particularly in treating physicians, that at the first visit the blood pressure is almost certain to read much higher than it does subsequently. This is due to nervous apprehension which either raises the blood pressure or tightens the artery so that it is hard to compress.

Blood pressure has a personality of its own. It applies individually and it is necessary in these days when people pass from one place to another and one medical advisor to another that they should themselves know their blood pressure peculiarities. The patient must be taken into the confidence of the physician and trained how to live according to his needs.

The periodical examination, if it ever becomes universal, will of necessity do away with the concealing of people's condition from themselves. I have always thought that concealment was wrong and it has long since became inapplicable to metropolitan practice. I can imagine it being practised by a kindly physician who is a father confessor in his small community. This is impossible in metropolitan practice where each person is in contact with many physicians and where medical matters are much the subject of casual discussion and where a fair number of medical men have adopted perfect frankness as their motto. This frankness of physicians is only a counterpart of the frank relations that exist between people in general. The young people of today do not very long burden their souls with any of Nature's secrets.

TREATMENT

In the treatment of blood pressure there are two elements to be considered, the relief of such concomitant symptoms as the person suffers from and the treatment of the high blood pressure condition. The latter is the task that comes to the hands of the heart specialist, the former is more the task of the general practitioner who takes care of the person in the interval between his visits to the specialist. Hence, my interest has always been more in the general regimen than in the relief of particular symptoms.

The occasional use of high frequency electricity for the relief of symptoms is justifiable and nitrites are certainly useful. Nothing serves better than training the high blood pressure subject to use one two hundred and twenty-fifth of a grain of nitroglycerin on all those occasions when he finds by experience that it makes him feel better. A single dose of nitroglycerin is often effective in the insomnia of arteriosclerosis. In people who are under observation for long periods of time, when the opportunity offers, it is a good plan to ascertain what their reaction is to digitalis. Another drug which can often be used, experimentally, to advantage, is theobromine and sodium salicylate, in small doses, five

or ten grains three times a day. It seems to promote the well being of some people with high blood pressure conditions and in these small doses it does not irritate the kidney or produce a disagreeable effect. Sodium iodide also acts well and is agreeable to some people. The excessive use of iodides makes many people very miserable and does no good.

In writing on blood pressure one must ever warn one's readers they are dealing with a symptom and not with a disease. Disorders of the heart and circulation have occupied the thoughts of the best medical philosophers of each generation of physicians as they have come and gone.

In our time the mechanistic theory is giving place to one founded upon cellular pathology and the study of infections and disease has become a matter to be considered in relation to the whole life of the individual. We labor to adjust what we cannot cure. On this basis much has been accomplished in the last twenty years and we can look forward to great things in the coming decades.

109 East Sixty-first Street.

A Critique on the Determination of the Size of the Normal Heart by Röntgenology

A. E. FOSSIER, A.M., M.D.

New Orleans

Professor of Medical Diagnosis, Graduate School of Medicine of the Tulane University of Louisiana.

The many controversial formulæ, methods, tables, etc., for the determination of the normal size of the heart by röntgenology, all barren of any practical results, are of little value to the clinician in diagnosing cardiac pathology.

The röntgenologist as well as the internist fully appreciates that the normal size of the heart is so variable, and depends so greatly on the sex, age, height and weight of the subject, that it is necessary for a basis of normality to be established, as the slightest modification of its size may reveal an underlying pathological condition. Unfortunately, in determining the size of the normal heart, radiology is of little value, and the physician who must rely absolutely on the röntgen rays to map out the area for him, or to measure the size of the transverse or longitudinal diameters of that organ, will frequently be given data which will lead him into error.

The transverse or longitudinal diameters, or the area of the cardiac silhouette, prove nothing, and mean little in recognizing the normality or any slight but significant enlargement of the heart until a basis for determining the normal size of the individual heart is established. In other words it is impossible either by teleröntgenography or orthodiagraphy, both of which give practically the same results, to state with any degree of precision that the heart is normal or pathological in size. While not altogether subscribing to the extreme viewpoint of the illustrious cardiologist, Sir James Mackenzie (1), I am bound to agree with his statement, in so far as it applied to the determination of the normal individual size of the heart. He writes: "Indeed I am doubtful if an x ray examination of the heart has ever thrown the slightest light on a cardiac condition." And continuing, "Like the modification of the stethoscope, the modification of the x ray methods by orthodiagraphy and teleröntgenography has been of little practical use."

The following are important pitfalls in the path of röntgenologists, which they have not as yet been able to evade in determining normal heart size:

1. The failure in most cases accurately to outline the apex and the superior and inferior contours of the heart.

Usually if the heart lies obliquely in the chest, the shadow of its lower third portion with that of its apex is obliterated by the denser shadow of the diaphragm, liver and other organs. All radiologists who have made a study of the size of the heart acknowledge that this is a great and I may even say an almost insurmountable source of error.

Alfred Cohn says (2): "The difficulty of locating the apex precisely in a photographic plate makes the estimation of the long diameter inexact." And further: "To delimit the area of cardiac shadow requires that the extremities of the lines representing the right and left borders of the heart be joined by curved lines drawn *arbitrarily*. With experience these lines are properly drawn by different observers in a consistent manner, but no doubt each observer draws them differently. But the complete outline fails in exact representation also because of the difficulty, indeed often the impossibility of locating the apex in certain persons. On being able to locate this point accurately depends the value of the measurement, both of the long diameter and the area."

Bardeen (3) says: "An accurate outline of the apex is the chief difficulty that confronts one when he attempts to complete a line to the lower border of the heart."

Vaquez and Bordet (4) say: "It is only in the pathological condition when the shadow of the heart is very dense that one is in a position to mark on the tracings the lines D G, corresponding to the base, and D′ G′, corresponding to the inferior contour. In the normal condition this is not the case, and the construction lines are simply *interpretive*. And so the calculation of the area can be only approximate" (Fig. 1). And very recently Hodges and Eyster (19) acknowledge the following: "Most of the workers in cardiac röntgenology agree that when properly controlled, either teleröntgenograms or orthodiagrams will give a reasonably accurate measurement of the frontal plane of the heart, in spite of the fact that by either method, the upper and lower borders

of the cardiac silhouette must be completed *empirically.*"

Yet this portion of the cardiac silhouette approximating one half and sometimes as much as two thirds of the cardiac borders, which can only be made out as stated by Cohn "arbitrarily," by Vaquez and Bordet "interpretatively and approximately," and by Hodges and Eyster "empirically," is essentially necessary in delimiting the size, shape and position of the heart by radiology. This indeterminable and obscure portion of the cardiac shadow has been arbitrarily used in every formula for measuring the area of the heart. From this conjectural delineation of one half to two thirds of the heart's borders, conclusions are reached as to the normality or abnormality of its size. From such inaccurate, conjectural and frequently absolutely wrong premises it is impossible to arrive at accurate conclusions. Yet this is only one of the most patent difficulties which render so arduous an approximately correct measurement of the cardiac outlines with the röntgen rays.

2. Divergence of the rays is always an important factor of error in the radiological measurement of heart size and area. The size of the heart is thereby exaggerated; but were this degree of amplification constant and the same in all cases, it could be easily corrected and would be a negligible factor of error, but as this exaggeration varies with the size and position of the heart it produces an artificial enlargement of variable extent. Bardeen (3) asserts that the most practical distance for teleröntgenography is two metres; he also maintains that at this distance there is a sufficient dispersion of the rays to make it necessary to allow for enlargement of the heart silhouette. According to Vaquez and Bordet (4) the distance of one metre, a metre and a half, or even two metres, gives too considerable exaggeration of the heart silhouette. That it is only at two metres and a half that the exaggeration of the heart's shadow is reduced to its practical minimum, that is, the projection of an object fifteen centimetres in size, is augmented by only four or five millimetres.

The extent of the increase of the actual cardiac dimensions in teleröntgenograms taken at the same distance, depends upon the bulk, shape and deformities of the chest and the thickness of its walls; also it increases proportionately through the size and position of the heart. This amplification is greatly reduced in vertical hearts (the long narrow heart commonly called drop heart) and proportionately increased in horizontal hearts (the broad oblique hearts called the squatty heart). It is apparent that this exaggeration increases proportionately with the size of that organ, for the narrower its transverse diameter the less will be the amplification, the wider its transverse diameter the greater will be the augmentation of its radiologic area.

3. The influence of respiration on the size and shape of the heart is marked, and unless the subjects examined are invariably radiographed in the same respiratory phase, it may cause an augmentation of the radiologic cardiac area.

Neuhof (5) writes: "An added consideration, tending to lessen the value of measurements as comparative standards is the difference produced by movements of the diaphragm. When the excursion of the latter is limited, less of the heart is uncovered, its ovoid contour appears flattened, and the transverse measurement is correspondingly enlarged. With a mobile diaphragm the reverse is usually true. From all these facts it is apparently impossible to establish mathematical orthodiascopic standards of measurements. This statement, however, does not preclude such general conclusions as that "normal" hearts may be usually large or small, or pathologically enlarged hearts often overstep the somewhat ill defined limits. There is naturally no doubt of the value of orthodiascopy in the determination of the marked variations in the size of the heart."

The following taken from the authoritative work of Vaquez and Bordet (4) emphasizes the possibility of error due to the respiratory phase: "During deep inspiration the heart follows the movement of the diaphragm and is lowered. At the same time, the organ changes a little in form and its diameters vary slightly; the longitudinal diameter increases and the horizontal diameter diminishes; the result is an elongation and a narrowing of the shadow of the heart. During deep expiration the contrary is observed. Under the pressure of the diaphragm, the heart is raised and spread; both diameters increase, the horizontal more than the longitudinal. Here, for example, are figures noted in the case of a normal subject thirty years old:

Average respiration	*Forced inspiration*	*Forced expiration*
Longitudinal diameter in cm. 11.5....	11.8	13.5
Horizontal diameter in cm. 11.5.....	11.2	15.1

The preceding considerations bear only on forced movements of inspiration and expiration. If the respiration is quiet, the volume of the heart, as Groedel has remarked, "does not change notably" (Fig. 2). From the foregoing it is seen that the transverse diameter of the heart may vary two to three cm. between forced respiration and expiration.

4. Another factor which considerably influences heart size is the varied individual changes in the size, shape and position of that organ occasioned by its systole and diastole.

Eyster and Meek (6) describe a method of making rapid x ray shadowgraphs of the human heart with a casette changing mechanism allowing two exposures within the same cardiac cycle. From their observations made on the normal heart they state that: "The decrease in size of the cardiac area during systole may involve any of the outlines, but does not usually involve all. The outline corresponding to the right auricle varies least in position, while the left ventricular outline, particularly toward the apex is the margin which undergoes as a rule the greatest movement. The border of the right ventricle nearly always shows a descent at the base. The part of the left ventricular border may likewise vary. Usually the maximum change is at or near the apex and decreases upward, but the reverse may be seen" (Figs. 3 and 4).

These observations explain the fact that the difference between the size of the teleröntgenograph and the anatomical heart is much less in the vertical than the horizontal heart. The greatest change in the size and shape of the vertical heart due to its systole and diastole is at its lower curvature, the apex being more to the right and down. As the

eart increases its obliquity, this difference in its size ıcreases upwards and to the left. This can be easily emonstrated either by percussion or with the röntgen rays by pressing the lower abdomen, which ıuses the heart to rotate upward and to the left, ıd its transverse diameter to increase. As the car-

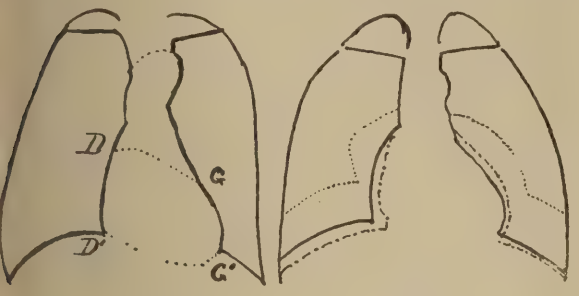

Fig. 1

Fig. 2

Fig. 1.—Orthodiagram of the heart and the large vessels in frontal sition. (*After Vaquez and Bordet*).

Fig. 2.—Black lines, quiet respiration; dotted lines, forced expiraon; dot and dash lines, forced inspiration. (*After Vaquez and ordet*).

ıac silhouette shows the heart in its diastolic aspect ıly, the changes caused by its systole must be ıerein included. This distortion in the cardiac ıadow cannot be contradistinguished or eliminated ıd thereby must be a source of considerable error determining radiologically the diameters, and the ea of that organ.

5. The shadows produced by extracardial structres, the pericardium, pericardial fat, and pericarıl bloodvessels are considered by radiologists an ıtegral part of the heart's silhouette, and they ignore ıe influence of this factor in the magnification of ıe size of that organ.

Hirchfelder (7) says that fat may be deposited in ıe heart in solid masses of adipose tissue, especially the pericardium in fat individuals, and particularly ı those addicted to alcohol, and it is very often assoated with coronary sclerosis. This condition is esignated as fatty infiltration or obese heart. He so mentions that in normal hearts there is a conderable amount of fat thirty to sixty grams (one to vo ounces), collected just below the endothelial yer of the pericardium, along the auriculoventricur and interventricular sulci, at the base, and scatred elsewhere over the heart. It has been shown W. Muller (8), Hirsch (9), Kirch (10), that the eight of adipose tissue may actually exceed the eight of cardiac muscles. G. Schwartz (11) called tention to this source of error from a radiological ewpoint and proved that the left cardiodiaphragatic sinus, instead of being clear, is filled by a ıadow, less heavy it is true, than that usually cast the heart. This he proved to be due to the presıce of fat.

The said fatty cushion surrounding the apex is also stinguishable from the cardiac tissue by percussion. This element of error will not invariably amplify e size of the cardiac silhouette and the extent of is exaggeration being so inconstant that it is beyond e scope of definite corrections. While this amplıation in some cases may be a negligible factor, yet other instances it may explain the great differences the size of the normal radiological heart. These elements of error and many others not enumerated in this article are the reasons for the difference in the size of the transverse diameter of the normal heart of the anatomists and of the röntgenologists.

The size of the transverse diameter of the normal heart handed down by the great Bouillaud (12) in 1841, and confirmed by other anatomists, averages approximately 8.8 cm. at its broadest. The greatest breadth of the normal heart, according to Gray (13) is 8.9 cm., according to Piersol (14) 9 to 11 cm., and to Morris (15) 8.7 cm. The radiological dimension of the transverse diameter of the heart is, according to Claytor and Merrill (16), 10.7 cm. to 13.8 cm. in men weighing from 108 to 181 pounds; according to Moritz (17) 11 cm. to 15.5 cm. in men between the ages of seventeen and fifty-six years; according to Lutembacher (18) 11 cm. to 13 cm. in men up to fifty years of age; to Bardeen (3) 11.4 cm. to 14.4 cm. in men weighing 100 to 200 pounds.

A consideration of the numerous statistical studies on the size of the normal heart, as determined in orthodiagraphy and teleröntgenography not only by the authorities quoted above but also by other röntgenologists, gives the dimensions of the transverse diameter to be from 10.7 cm. to 14.4 cm. If this difference between the dimensions of the transverse diameter of the anatomical and röntgenological heart were unvaried and equal in every case, or even in any one group of cases, then it would be a simple matter to make the necessary corrections; but as this difference is always variable and depends on so many conflicting factors, it must remain an outstanding insurmountable difficulty to determine accurately the standard size of the individual normal heart by röntgenology.

We can safely predict that unless these sources of error are corrected all attempts to determine the normal transverse diameter of the heart, which is the

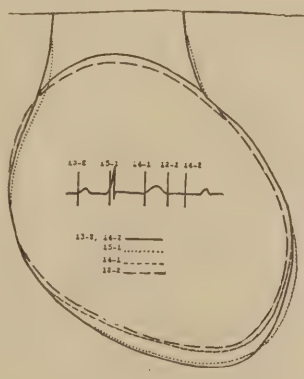

Fig. 3

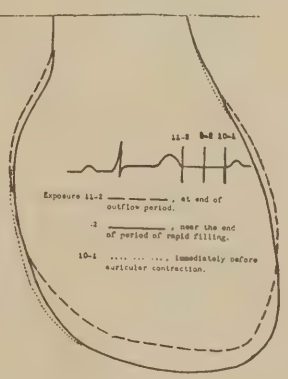

Exposure 11-2 ——— , at end of outflow period.
, near the end of period of rapid filling.
10-4 ..... , immediately before auricular contraction.

Fig. 4

Fig. 3.—Changes in outline of human heart during contraction. (*After Eyster and Meek*).

Fig. 4.—Filling period of human ventricles. The three x ray exposures were made as shown by electrocardiograph record. (*After Eyster and Meek.*)

only diameter which can be actually delineated and not guessed at from the röntgen silhouette, will be unsatisfactory and barren of conclusive results. And as even this diameter cannot always be correctly determined from the cardiac silhouette, it is evidently impossible to compute with any degree of exactitude the area of the volume of the heart by radiology. In consequence it can be asserted that a very large

percentage of the cardiographs, either teleröntgenography or orthoröntgenography, are useless and even misleading.

Hodges and Eyster (19) have recently written: "The use of the röntgen ray is therefore clearly applicable to the study of the changes in heart size in a particular individual, and it is only when we come to the subject of absolute size that serious divergence of opinion exists. Some workers hold with Bertnard Smith that the size of the human heart is delicately adjusted to stature and body weight. Others, like Smith and Bloedern, feel that individual variations are so great as to make the method entirely useless. Still others, among them Bardeen (3), feel that while certain variations from a mean size have to be considered, sufficient accuracy is obtained to be of practical value."

As long as there exist the cardinal factors of error enumerated above, which are the basis of all formulæ, tables, etc., for determining the exact size of the normal heart by röntgenology, so long will this means of estimating the normal cardiac size, area and volume in men be fallacious, misleading and inaccurate. This statement is applicable also to the latest contribution on this subject by Hodges and Eyster (19). They summarize their work as follows: "New tables are given for the estimation of normal cardiac area in men. These are derived from the formula: Area in sq. cm.=age 0.0204=stature 0.8668+weight 0.337 minus the constant 63.8049. If the heart is found to be seven square centimetres larger than the predicted area the chances are three to one that is actually enlarged. With fourteen square centimetres the chances of pathology are ten to one, and with twenty-one square centimetres, forty-five to one."

Their formula is based on the same sophistry, because they qualify their conclusions with the statement that the "upper and lower borders must be completed *empirically*," and also by "after correction for the distortion due to divergence of the rays."

How can the size of the normal individual heart be determined? Is there a basis by which it can be ascertained? In a previous article I have endeavored to show that percussion gives an accurate delineation of the heart size, shape and position. A tabulation of the normal hearts of two hundred and fifty-seven soldiers percussed standing showed that the total average of the size of the transverse diameter of those organs to be 9 cm. and of the longitudinal diameter 9.27 cm.

The transverse diameter corresponds to the greatest width of the heart, and the longitudinal diameter begins at the intersection of the right contour of the heart and the origin of the great bloodvessels and extends to the apex. It was noted that the dimensions of the transverse diameter of the heart at its broadest corresponds to the measurement of this same diameter given by anatomists.

The most important diameter of the heart is the transverse, the longitudinal is important only in so far as it agrees with the size of the transverse. A heart well supported by the diaphragm and lying obliquely will have a transverse diameter about equal to the longitudinal, but a heart that is pendulous and elongated, as is commonly found in the hyposthenic or splanchnoptotic type of person, will have a larger longitudinal than transverse diameter. These obse vations are confirmed radiologically by Vaquez an Bordet (4), who write: "In the recumbent positio as we have said, the two diameters, longitudinal an horizontal, are perceptibly equal. Sometimes, hov ever, the first is greater than the second by from fiv mm. to about one cm.; in exceptional cases it is les by several millimetres. In the standing position, th longitudinal position may be increased a little, whic is, however, very rare; on the contrary, the horizo tal diameter always diminishes. It then becom inferior to the other by from five mm. to one cm.

Percussion (20) gives two distinctive lines of du ness, one corresponding to the x ray silhouette of th heart and the other to a more pronounced area d dulness, the size of which equals the normal hea size during its systole; the former corresponds to th heart's margins as mapped out by the x rays, an represents the heart in diastole, together with i pericardial appendages, including extrapericardi fat and bloodvessels, and is subjected to the sam inaccuracies and is just as unreliable in its resul as the x ray silhouette. This difference between th two margins of dulness is wider usually on the le heart border than on the right. As in the röntgen graph, and for the same reasons, it varies in size i different persons when delimited by percussion. Th difference may be as much as 1.5 cm. to three cm. persons having a high diaphragm in whom the hea lies obliquely; it also diminishes in size in perso having a sagging diaphragm, which causes the hea to assume a more vertical position. Therefore, th only practical way of delineating the size of the no mal heart must be during its systole; this can b easily done by percussion, and only with extrem difficulty by röntgenology.

From an observation of many hundreds of norm hearts during the past ten years, in nearly every ca I have found a constant correlation of the size of th fist to that of the heart percussed in systole (its inn margin of dulness); in other words, there is a ve close approximation of the size of the clenched fi to that of the heart in systole. This was first o served by Laennec, and is confirmed by more mode authors on anatomy. Davis (21) says: "The hea is somewhat larger than the clenched fist." Cunnin ham (22) writes: "It is roughly estimated as bei about the same size as the clenched fist." The clo approximation of the size of the normal percuss heart in systole to the measurements of that org given to us by anatomists has been mentioned befo in this article.

The transverse diameter of the heart correspon to the linear measurement of a line beginning at t junction of the inner side of the right clenched f and the wrist, and ending at the middle joint of t fourth finger (23). The stature of a person, t work he performs, bears a close relationship to t size of the hand. This measurement is an accura factor in determining whether the heart is normal size or whether there is a slight modification in t measurement of its transverse diameter. As the d termination of the size, shape and position of t heart is a dominant factor in the diagnosis of pathological condition, this method has proved great importance in the recognition of cardiac d eases.

A Case of Transposition of the Great Vessels of the Heart With Atresia of the Aortic Orifice

FRANCES M. JOHNSON, M.D.

Philadelphia

Case.—A male baby apparently normal until late the second day of life. At that time he grew restss and gave repeated shrill cries. Later his breathg became labored and rapid, reaching seventy-six spirations a minute. He was pale, only slightly anosed, and the temperature fell to 96° F. Stimution increased the temperature but other symptoms mained, and he died early the next morning with morrhage from the nose and mouth.

The mother was colored, thirty-one years of age, ho had had eight children. Of the other children, e are living and well; two died of influenza in)18. There was no history of miscarriages. Wasrmann was negative. This pregnancy was uncomicated and the delivery was normal.

Autopsy revealed marked congestion of liver and leen, with petechial hemorrhages in other abdomal organs, but no abnormality in formation of these gans. The thymus was enlarged, the gland weighg thirteen grams, and was increased in size, chiefly the anteroposterior diameter. The lungs showed arked areas of congestion. The heart was dilated, tending from the midclavicular line on the right the midclavicular line in the fifth interspace on the ft. There was edema of the brain but no hemorage.

On special examination, the heart was found to nsist of a broad base and rounded apex, the latter ing composed of the left ventricle. In the right per quadrant of the anterior surface there was a oove running obliquely downward from left to ght. This marked the interventricular septum cutig off a muscular shoulder which represented the lastic right ventricle. The two great trunks nerged from the anterior surface of the base in the median line between the two auricular appendages. The trunk occupying the position normally occupied by the pulmonary artery emerged from the conus of the right ventricle in the median line and passed directly upward for a distance of 2.5 cm. There it gave off three branches to the head and upper extremities. It was a small, thin walled trunk measuring 0.75 cm. in circumference, and was the transposed aorta. On laying it open two large branches were found to rise from the coronary sinuses and pursue the course of the greatly dilated right and left coronaries. The aortic orifice itself was atresic, the valves being fused along their contiguous margins except for a small central chink which was blocked by the musculature below.

The transposed pulmonary artery arose directly to the left of the aorta on a slightly posterior plane. It passed directly upward, giving off a large branch to either lung and then continuing onward through a wide channel which represented the patent ductus arteriosus, to form the large descending thoracic aorta. The patent ductus and the small transposed aorta joined each other at an acute angle.

On laying open the heart, the right auricle was found to be hypertrophied and dilated and presented a large patent foramen ovale. The tricuspid orifice was aplastic. The right ventricle showed an aplastic cavity about 1.0 cm. in diameter with musculature 1.25 cm. thick, yellowish in color and apparently diseased. The conus was obliterated. The left auricle was dilated but smaller than the right. The mitral valve was normal. The left ventricle contained a large roomy cavity with a wall 0.5 cm. thick. The pulmonary orifice was 2.75 cm. in circumference.

The Use of Diathermy in Cardiovascular Diseases

BARUCH LAST, M.D.,
New York

GENERAL EFFECTS OF DIATHERMY

Before we discuss the application of diathermy and the effects produced by it in this group of diseases, I wish to state the effects of diathermy in general and how these effects are produced. .

The effect of diathermy is in the first place perceived and demonstrated as a warming up of all the tissues through which the current passes. The rise in temperature is from one to seven degrees F., in my experience; others have observed still higher values. The warming up is accompanied by a marked hyperemia embracing all the tissues. The main action of diathermy is due to the active hyperemia it produces. Bier describes the action of active hyperemia as stimulating resolution and absorption, as analgesic and as bactericidal. All these effects can be achieved by an active hyperemia produced by any means, as by the direct application of heat, the difference being that with the direct application of heat, whether by means of hot compresses, a hot water bag, or hot air treatment, reddening of the skin is greater; hence the hyperemia of the skin is more intense. When diathermy is applied, the skin is only slightly reddened, or sometimes not at all. This leads to the conclusion that in the latter case the heat is distributed into the deeper tissues. This can easily be proved by the fact that after a transverse application of diathermy to the pelvic region, with electrodes of equal size applied in front above the symphysis pubis and in the back directly opposite this one, an increase in the temperature will be registered by a thermometer inserted in the rectum or the vagina, although the skin may show little evidence of hyperemia. Many more observations and experiments could be cited to prove that diathermy produces an intensive active hyperemia in the deep tissues, but suffice it to say that, in comparison with the direct application of heat, diathermy produces a hyperemia which penetrates all layers of tissues and organs with much better control as far as the intensity, the location and the direction of the desired hyperemia is concerned. The patient experiences no pain, not even the slightest discomfort, while being treated, nor are there any undesirable after effects.

The electric current as such has only a secondary action. The stimulating and chemical action characteristic of the galvanic and of the alternating currents of low frequency (faradic and sinusoidal) are totally absent in this form of electric current. But the high frequency current has an analgesic effect. It is possible that the analgesic effect of diathermy is partially due to the high frequency current, as is evidenced by the fact that the nonheat producing, pure D'Arsonval current is also analgesic in its action. This point of view is strongly defended by Kowarschik of Vienna. That there is an effect due to the electric current is still more plainly evident when we remember that the pure D'Arsonval current reduces high blood pressure to almost the same degree as does the application of general diathermy.

These facts should convince us that the action of diathermy is due first to the hyperemia it produces and, in a lesser degree, to the electric current. It is selfevident that if the action of diathermy is mainly due to its ability to produce a hyperemia, then its effect upon cardiovascular disturbances must be considerable. Truly we have a great number of these disturbances benefited by the action of this modality of the electric current.

DIATHERMY IN HEART DISORDERS

Let us now first consider the diseases of the central circulatory system and then of the peripheral. Of the diseases of the heart those that are accompanied by pain are readily amenable to this form of treatment. Cases of myocarditis due to disturbances of the coronary arteries are the first to be considered. Cases of myocarditis of not long standing, accompanied by a feeling of oppression, painful sensations around the cardiac region, and occasional attacks of angina pectoris, are benefited by this form of treatment. It may not be successful in one hundred per cent. of the cases, but in each and every case included in this category diathermy should be given a trial, especially when about five treatments will undoubtedly tell whether a course of treatments will be beneficial or not.

There are certain symptoms and physical signs which, after five treatments, will be a positive indication of the advisability of continuing the treatment. If there is a partial cessation of painful sensations and of oppression; if there is a lowering of the pathologically increased blood pressure, not only after each treatment, but is also less at each consecutive treatment, so that there is a steady lowering of the blood pressure value without exaggerated fluctuations, we may be sure that we are dealing with a case that is going to respond. If these things do not occur nothing should be expected of the treatment and it should be discontinued.

The following is the technic of the procedure. Two metal plates of nearly equal size should be used. The slightly smaller one, four by six inches, is placed in front over the precordium, and the larger one, five by eight inches, in the back exactly opposite the first one, the patient being in the prone position. The current applied should not exceed one ampere even if the patient does not feel the heat, as the maximum dose is unnecessary and might even be harmful. The duration of the treatment should be from ten to fifteen minutes, never longer. The patient should be allowed to rest one half to one hour after the treatment. The pulse should be counted and the blood pressure taken before and after treatment. The pulse rate increases in some cases after the application and the blood pressure is lowered in all cases. The treatment should be given every other day and the entire course of treatments in the responsive cases should number twelve to twenty until the symptoms subside.

The same technic is also applicable with good re-

sults in cases of valvular diseases accompanied by pain, and in cases of chronic pericarditis with adhesions. In the latter cases a trifle stronger current may be used, and the treatment may be continued for a longer period if necessary.

DIATHERMY IN HYPERTENSION

The effect of diathermy on high blood pressure has already been mentioned in connection with coronary disease. There is no doubt that a reduction of high blood pressure follows this treatment. The treatment is especially of great value in the early presclerotic cases with moderate tension, as without doubt it postpones the sclerotic stage for many years. It is understood that cases of hypertension due to a certain definite anatomical cause, such as aortic aneurysm, no permanent objective results are to be expected, although certain temporary improvement of subjective symptoms such as pain oppression and sleeplessness occurs.

The best method of applying general diathermy is by the contact method, by means of five electrodes. One square electrode of a large size is placed on the back of the patient and is connected to one pole, and the other four are placed in the form of cuffs one on each extremity, and all connected with the second pole. General diathermy can also be applied by means of Dr. Schnee's four cell bath. By these two methods we achieve a relaxation of all the peripheral bloodvessels and the blood stream gets the most heat. The heat is then carried by the blood stream throughout the entire body. That the bloodvessels are getting the most heat can be proved by the fact that a thermometer held in the axilla near the artery will register a much higher temperature than a thermometer inserted into the rectum.

There are two other ways of administering general diathermy; first, autoconduction by means of the autocondensation pad, and secondly, the induction method, by means of a solenoid. By these two methods much current is being wasted and they should only be used if exudates of large capacity are to be affected, which could not be treated by the contact method.

The duration of the treatment by the contact method should last at the beginning fifteen minutes, then twenty minutes, then twenty-five to thirty minutes, and two and one half amperes can be given without any untoward effect. The course of treatment should comprise fifteen to twenty treatments.

Arteriosclerosis of the abdominal vessels is to be treated in the same way as coronary diseases, with the electrodes placed one on the abdomen and the other on the back, one and one half amperes for fifteen to twenty minutes should be given for fifteen to twenty treatments.

PERIPHERAL DISTURBANCES

The following cases of disturbed peripheral circulation are amenable to treatment with diathermy.

Different angioneuroses, frost bite, habitual cold hands and feet, angioneurotic edema, elephantiasis, Raynaud's disease, endarteritis obliterans, and thromboangitis obliterans.

There are two classes of angioneurosis. The first is characterized by an exaggeration of vascular tonicity—angiospasm—and is accompanied by paresthesia and pain, and the second is characterized by a lowered tonicity—angioparesis—recognized by cyanosis, sensations of cold and other sensory disturbances, which in their further development may lead to serious disturbances, such as trophic changes and eventually to gangrene (Raynaud's disease).

Frost bites resemble, clinically, angioparesis and may exhibit all the symptoms; in mild form, cyanosis and sensations of cold, tingling, etc.; in more severe cases, trophic changes, blebs and ulcers, and in the extreme cases, gangrene.

Habitually cold hands and feet belong also to the group of angioneuroses, as does also angioneurotic edema.

Elephantiasis, the sporadic type, which usually starts from some circulatory disturbance which leads to the disturbance of the lymphatic circulation, is also amenable to this form of treatment, as there is also an increased circulation of the lymph, with the hyperemia.

Erythromelalgia which also belongs to this group of vasomotor disorders, might be responsive to the treatment with diathermy.

Raynaud's disease, a vasomotor disorder without organic disease of the vessels, responds quickly to diathermy. Subjective symptoms disappear first, then mobility becomes easier, then cyanosis disappears. In the more severe types of the disease we can postpone gangrene for many years. The treatment has to be continued for many months.

Endarteritis obliterans—no matter whether found in elderly persons, in diabetic subjects, or in connection with arteriosclerosis due to any cause whatsoever—responds to diathermy. The symptoms in these cases are: feeling of cold, discoloration of the skin, cyanosis, pallor or redness, tingling, numbness, pain in the muscles, interference with motion, such as intermittent claudication, and finally trophic changes from blebs, fissures, ulcers, gangrene. These patients without treatment or even sometimes with treatment, are growing progressively worse. There is a definite pathology of the bloodvessels, starting in their adventitia and leading to the obliteration of the lumen.

All the cases of this group respond to the treatment under discussion, as long as the pathological process involves only the arterial side, without any evidence of an involvement of the capillary or venous systems, such as numerous nets of collateral, distended or thrombosed venules or veins on the skin. When the skin of the involved extremities shows such veins—in my experience—no relief can be expected from diathermy. In other words, we can lay down the following rule: All cases of endarteritis obliterans will respond to the diathermy treatment so long as the pathological process is limited to the arteries, without the involvement of the capillary or venous systems.

The technic of applying diathermy in all cases of peripheral circulatory disturbances is by means of the longitudinal method. In the longitudinal method of application, in contradistinction to the transverse method, in which the current is forced to pass through all the tissues and the tissue of the highest resistance gets the most heat, the current follows the paths of least resistance and these get the most heat. As the paths of least resistance are

the blood and the bloodvessels so it is evident that we are attacking the seat of the trouble.

The strength of the current is anywhere between 0.3 to 0.7 A. and the duration fifteen to twenty minutes. The treatments are being given daily at first, and then every other day and finally twice a week. A series is twenty treatments, which may be repeated if symptoms recur after a certain time.

In conclusion let us consider the physiology of the action of diathermy in vascular disease. In all probability the course of events is as follows: the blood is the carrier of the heat produced. The blood gives up its heat to the vascular walls, which contain the sympathetic nerves. These in turn are very sensitive to heat as they have no sheaths and react to the warmth by relaxing the vascular walls. This relaxation causes also a widening of the lumen of the vasa vasorum, and the vascular wall gets more nourishment and is kept in a healthier state than before. A more normal vascular wall responds more normally to the nervous and chemical impulses and hence the benefit of this treatment in the above mentioned disturbances. The action of diathermy rests on a definite physiological basis and is not suggestive, the best proof being that no purely nervous disorder of the heart responds to the treatment.

Vascular Disturbances

LOUIS L. TEN BROECK, M. D.

Minneapolis, Minn.

The periodical examination made on Army officers affords an unexcelled opportunity to measure the consequences resulting from stress and strain. Individual examples from our former statesmen are tragically impressed upon our memory. It seems that the demand of modern civilization is so complex that only supermen can continue at the helm of the State, and they too soon give out unless we can further fortify them against the consequences of stress and strain. A short while ago preservation of the human race demanded that medical science conquer the problem of contagion; now the major requirement is that medicine cope with the preservation of virility and extend the same beyond those years now known as middle age.

To this problem such observations as have just been made must lend much that is of import. The general findings quoted show a diminution in ability for sustained effort both physical and mental. In the more severe cases the effects seem to gravitate into the realm of the neuropsychiatric. The only constant prevailing objective sign so far disclosed points to a disturbance in the vasomotor sphere. This is interesting because the final ravages of stress and strain are admittedly written in retrogressive changes in the median coat of the bloodvessels (1). The observations referred to simply reveal morbid disturbances at the same site, but at a far earlier stage. This is certainly a logical relation since the admitted change in the muscle media must at some time exhibit a dynamic impress preceding an anatomical one, one manifested by distorted contractions. Where we formerly wrote sclerotic, we now say dynamic, the condition met with in early stages.

The tendency to weld clinical practice and anatomical diagnosis into one concept and terminology is based on a laudable desire for exactitude. In the field of contagion, because microbes from the start leave their impress through anatomical changes, this welding process was desirable; but in this new field of conservation we are concerned with disease manifestations that have yet to leave their imprint on anatomy until a later stage. When we examine writings on arteriosclerosis, we find ample confirmation of this practice. The richness of pathology of that disease is in marked contrast to the paucity of information concerning pathogenesis and what can be accomplished in therapy. If we are to cope with arteriosclerosis it must be at a period before there is little or any change registered in anatomy. The median coat must, therefore, be the pivotal point around which studies will centre and such studies will be concerned not so much with anatomical appearance as with muscle reactivity.

Such muscle as goes to make up the median coat takes part in the formation of five major systems: alimentary, bronchial, vascular, genitourinary and uterine. The similarity in structure of those muscle systems is in marked contrast to the dissimilarity in reactivity to disease and to drugs. Adrenalin, for example, exerts a marked tonic action on the bloodvessels, a slight action on the alimentary muscles and an opposite action on the bronchial system. Pituitrin exhibits its greatest tonic action on the uterus and intestines. The more we study, the more markedly is this selective action of chemicals on smooth muscle disclosed (2). If we further consider the phylogenetic history of these fibres we find them the primordial structure of that group, neuromuscular, the seat of a triangle of functions known as conductivity, contractility and irritability. Even in the human ureter the muscle fibres preserve this primordial, cell to cell conductivity. But before this type of conductivity is established it is preceded by a system of conduction by specific chemical substances, as stimuli, which reach their objective through the circulation. Thus, chemical stimuli and muscle response are the forerunners of what later becomes a complex nerve muscle system. As with conductivity, so with this primitive system; smooth muscles preserve it in an unchanged reactivity to chemical influences. It is this conception that we seek to stress because once established it brings the bloodvessels into the position of a barometer for chemical imbalances which eventually result in a loss of virility that permits of no restitution.

It is true that every cell exhibits a chemical reactivity, at times specific (3). Uranium picks out the kidney cell and produces the symptom complex of

nephritis. One also meets with group characteristics. Certain chemical radicals (somnifacients), reacting on the nervous system have their activity enhanced in proportion as their compounds are miscible with lipoids. The endocrines, too, show a reactivity to chemical influence. The iodine intake affects thyroid activity. We stress the reactivity of bloodvessels because it is more clearly depicted in recognized symptom complexes; and in addition, the chemical problems involved are less complex.

The interrelation of chemical and symptom complexes is of supreme importance in the study of certain somatic disturbances (4). In certain fields chemical progress has reached the point where analysis alone can make the diagnosis of a disturbance before it is clearly impressed on the clinical symptoms (basal metabolism). So sensitive is chemical diagnosis when properly developed that it detects disease at a period in which therapy is far more applicable. The problem of vascular disturbances is not fortified with a chemical understanding so applicable. We must depend on the combination of symptoms and our chemistry will generally prove to be suggestive rather than conclusive.

Symptoms provoked by vascular disturbances derive little elucidation from direct observation on the vessels. By analogy we would expect three degrees of reactivity: collapse, tone and spasm. Intermediary we recognize hypotone and hypertone, and two types of spasms—one sustained or tonic and the other intermittent or clonic. These degrees and types are well recognized in the alimentary canal. Furthermore, a study of the sense perceptions registered concurrent with changes in the degrees of alimentary muscular reactivity reveals a striking parallel, ranging from the realm of the subconscious through appetite, hunger, to pain (5). The explanation of this phenomenon is a task for physiologists. Our problem is to determine whether this principle is applicable to bloodvessels. If so, vascular reactivity of itself, registers in part at least its own symptomatology as well as those secondary symptoms which result from the disturbances within the organs the seat of vascular reaction. Shock is associated with collapse and spastic bloodvessels originate pain (migraine). Furthermore, vessel tone falls with a rise of hydrogen ion concentration, at least within certain limits. This is interesting as in many cited cases of asthenia symptoms, fluctuating with a variation of hydrogen ion concentration, are exhibited.

The secondary disturbances in the function or in the state of being of an organ, the seat of vascular distortions, are not uniformly distributed, but depend upon the part played by the vascular supply. Thus, not all tissues are equally dependable upon the blood supply for nutrition. The brain perishes in a few minutes, while bone retains its vitality for hours. Hence, it is in the nervous system that these secondary disturbances should predominate. So prompt do nutrition disturbances follow interruption of the brain blood supply that a train of symptoms is soon encountered quite suggestive of such symptoms as are met with in sclerosed bloodvessels. In addition, the vascular system plays an important part in heat regulation, and thus comes in close relation to the splanchnic area and the muscle system, in which regions symptoms are prone to appear. Blood profusion determines excretion and blood supply fluctuations will effect variations in excretion (urine). The problem is approachable from an entirely different angle, namely, a comparison with those symptoms following sclerotic changes. A close parallel is observed. Certain organs, however, like the kidney, bear a double load of vascular disturbances and direct insult of the fundamental chemical distortion. Brain, heart, muscle, splanchnic area alike are sclerotic and dynamic disturbances are the systems most frequently involved in symptomatology.

1. Symptoms in the central nervous system: sensory—cranial and optic migraine, tinnitus aurium, vertigo; motor—transient and mild disturbance of accuracy, skill and coordination; reflex—generally heightened; psychic—asthenia, inability for sustained effort, attention below par and frequently forced, memory for recent events for the same reason below par; insomnia. Insight is excellent and the patients detect something wrong long before it is manifest to others. Keen insight produces anxiety which can be augmented to phobias. We are constantly meeting with patients who after the correction of chemical imbalance, cannot tell what they worried about.

An extensive experience (war) with the cardiovascular systems disclosed an intimate association between tachycardia and vascular instability. Later we found an associate chemical imbalance in many cases. Any change in vascular tone in one area not compensated by a complementary change in another must throw the heart out of rhythm, just as a slipping of a clutch causes the motor of an auto to race. Fluctuations in blood pressures are met with along with cold extremities, hot and cold flashes and cold sweats (6).

Instead of claudications we meet with ill defined muscle aches and pains which when improvement parallels restoration of the chemical balance, we are tempted to attribute to a primary vascular disturbance. The splanchnic area is the seat of various disturbances formerly called dyspeptic but now described by a term of less meaning, neurotic. We know that some of the parenteral ferment activities (glycogenetic), are repressed during chemical imbalances. If a similar repression occurs in enteric processes (such as change from zymogen to enzyme) we can better understand the frequence of digestive disturbances.

The phobias encountered may rise to a level of a true psychosis, but no patient should be classified as psychotic until he has been proved to be free from chemical imbalances. The psychoses are a tertiary reaction and further complicate the symptomatology (7).

The study of chemical complexes at once involves us in difficulties that arise by reason of the shortcomings in medical chemistry. Deviations from normal chemical proportions or the occurrence of foreign substances we call chemical imbalances; where several of these chemical distortions are associated with definite and related symptoms we denote such a chemical condition as a complex (state of basal metabolism). The major portion of medical chemistry is limited to imbalances. In two instances (thyroid and pancreatic diabetes) the chemical findings are so conclusive as to constitute a complex.

Certain chemical findings quite constant and suggestive are met with in rabbits whose livers have been partly destroyed by an infecting coccus (coccidium hepatis). These show a low alkali reserve due to an accumulation of aminoacids, which the liver fails to convert to urea. Sugar curves are disturbed, high levels quick to appear and sustained on feeding while low levels predominate in starvation. Insulin fails to desugarize the food in proportion to its dose. These sugar abnormalities are laid to a repression of the glycogenetic function. Furthermore, the nervous instability of these rabbits and the ease with which they tire are suggestive of symptoms encountered in individuals with like chemical findings. In view of the importance of the liver the development of chemistry to a point where we can possess knowledge of a chemical complex indicative of liver deficiency (as we now have for the islands of Langerhans) will be a decided advance.

The study of chemical imbalances is inseparably connected with symptomatology, uncorrelated with symptoms they have a questionable significance. A better understanding of these imbalances and certainly a rational therapy will follow a knowledge of the provoking causes. Exogenous sources arise from the ingesta either through deficiency (iodine deficiency in goitre, avitaminosis) or from substances rendered toxic without the body as the diamines or ptomaines. The ingesta is also subject to bacterial activity within the food passages, wherein substances arise provoking a chemical imbalance. The bacteria may fasten themselves on these passage walls as focal infections, discharging substances provoking chemical imbalances or they may invade such chemical laboratory as the liver (see above) and provoke chemical distortions of great magnitude. These bacteria are markedly characterized by their habitat. The performances of the intestinal group are further complicated by the arrangement of the portal stream which brings the liver markedly under their influences.

The bacteria of the air and genitourinary passages concerned with the causation of remote effects, are dominated each by a morphological group, pneumococcic, streptococci, and the colon group, respectively. The part played by focal infections of these groups on vascular disturbances has been well demonstrated (8). Thayer has described such disturbances in typhoid and we encountered in convalescents from influenza numbers who showed transient and very debilitating attacks of tachycardia with a high blood pressure (approaching 170).

Morphological studies of the intestinal flora fail to simplify the complexities of intestinal infection, as is the case with air and urinary passages. To cut the Gordian knot we proceeded with biochemical investigation, making comparative analyses of the gases derived from incubated stools and those obtained direct from collection of the flatus (9). The noted differences we interpreted as due to changes in the active flora in response to change in the oxygen tension. If such a hypothesis is correct, augmenting the oxygen tension involved should reduce fermentation, and this can be proved to be true. So while affording no morphological group that dominates bacteria growth it may prove that a biochemical group dominates the intestines. Another phenomenon came to light during extensive fluoroscopic studies, namely, barium patches persisted at sites where a gas bubble and signs of muscular distortions had been observed. This was interpreted as dependent upon some epithelial reaction. No parallelism could be established between the intensity of the fermentation or muscular distortions, and the severity of remote symptoms.

The determining factor we were led to attribute to the state of the epithelium which stands between the heterogeneous mass of putrid products and nutritive products on the one hand and the liver on the other. Once this epithelium becomes remiss in its duty the liver functions deteriorate. Both epithelium and liver have the same phylogenetic origin and retain many parallel functions. Colitis need be no more exudative than rhinitis and both show a dry type with adherences, a type McCollom described in his studies on the colon. As a corollary we must look to the restitution and preservation of this epithelium as an indispensable factor in therapy at least at one stage of chemical imbalances originating from intestinal fermentation. The removal of bowel contents to the further deterioration of epithelium is a costly procedure. Thus, what starts out to be a problem concerned with bacteriology soon becomes complicated by many chemical and physiological factors.

Chemical imbalances arising from endogenous sources are traceable to three factors: a, such toxemias as pregnancy produces; b, parenteral digestion (protein fevers, traumatic fevers, anaphylaxis); c and primary metabolic disturbances (cretins, involutional states). The field of parenteral digestion is a pauper among the rich fields of immunology. Parenteral digestion of large exudates (autolysates) greatly enhances both the morbidity and mortality of primary infections and sterile autolysates can be shown to be more lethal (through vasomotor collapse) than the infected exudate from which they are produced.

When our knowledge of chemistry increases we will have a better therapy for some of the baffling problems in infections. Metabolic disturbances secondary to chemical imbalances (iodine deficiency and goitre) or bacterial invasion (see above, intestinal fermentation), add complexities to these factors yet are better subject to comprehensive analysis than those arising primarily (i. e., the involution states).

It remains to interpret those chemical findings which deviate from normal but whose correlation to disease wants further elucidation (chemical imbalances). In establishing that correlation to disease a helpful criterion lies in the determination of whether or not progress in therapy is accompanied by approach to chemical norms, i. e., if we are to use, say the alkali reserve as an index of disease the severity of the symptoms involved should fluctuate with alkali reserve. Our experience with many cases of migraine verifies this principle. In certain cases we can predict a migraine attack or its recession by chemical determinations. Chemical changes seem to keep one jump ahead of symptoms. Another helpful guide lies in the determination of the causative factor.

(To be concluded)

Historical Medicine

Living Long and Breeding Well as Plato Saw It and as We See It

JONATHAN WRIGHT, M.D.

Pleasantville, N. Y.

The perusal of a book (1) on the legend of Socrates and the origins of Plato a short time ago moved me so that I sat down to write an eulogistic criticism of it. It seems as though some one should write such a book or a book with such a subject at least, but as I read I found my criticism running into a vein not entirely eulogistic. Gradually the prejudice I have shared with the world for Plato and which the world has entertained almost ever since he walked the streets of Athens seemed to be leading me into quite an uncritical state of mind. All men regret to see their illusions attacked even when they know they are illusions, but I found myself quite unable to look upon the Platonic Socrates as a myth or upon Plato as having borrowed all he knew and all he contributed to the intellectual storehouse of the world from predecessors. We have known and loved the Platonic Socrates and he has occupied a pedestal scarcely if at all inferior to that of Confucius and Buddha and his figure in our world looms large to us, second only to that of Christ. From the point of view of prejudice alone I found myself revolting at the author's endeavor to drag our idol down to the commonalities of everyday life and taking up so much space in my notes to do so that when I sent off to some editors a pair of manuscripts, which they have reluctantly consented to publish, I found I had turned down my notes on the medicine of Plato which I had intended to incorporate as a sort of addendum to what I have said in a rather desultory way in the columns of this journal.

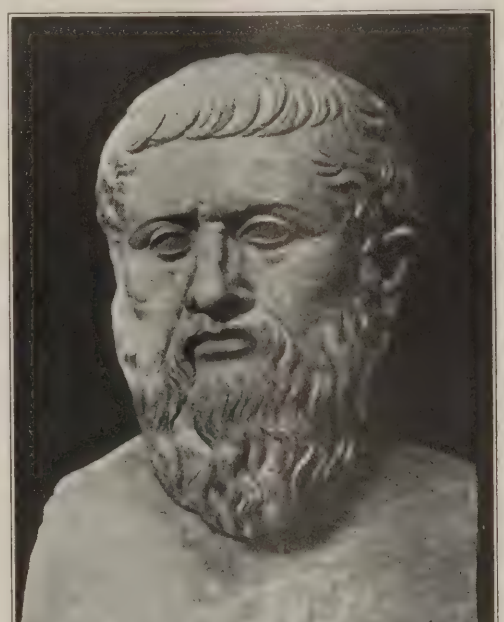
When, however, I look through the files of the Medical Journal and Record I fail to find what I was expecting—an essay of mine on Plato to which I had expected to make this a sort of sequel—and I am going to take up in this way what I have to say further in regard to the medicine of Plato at the point of some remarks I made on a certain theme in an essay on Herodotus last year (December 1923). To do so I break into the running discourse of the *Republic* which will carry us to the discussion as to the wisdom of lengthening life.

"Asclepius exhibited the power of his art only to persons who, being generally of healthy constitution and habits of life, had a definite ailment such as those he cured by purgations and operations and bade live as usual. In this he consulted the interests of the state. But bodies which disease had penetrated through and through he would not have attempted to cure . . . He did not want to lengthen out useless lives or to raise up puny offspring to an enfeebled sire. If a man was not able to live in the ordinary way he had no business to cure him. This was all in the interest of the state." (407) This is in line with the myth of Zeus punishing Asclepius and other medicating heroes for bringing man to life again. The doctors in the Iliad considered that sufficient which they did for Menelaus and Eurypylus and they did not think it worth while to tell them what they should eat or drink afterwards. Nestor's handmaiden, Hekamede, gave Machaon, a son of Asclepius himself, a mixed drink that was well calculated, we would now think, to lay low the stoutest digestion. The doctors who know what sickness is in their own bodies, those who have had the most diseases, "cure the body with the mind and the mind which is or has become sick can cure nothing." To avoid criticism I have followed Jowett's translation, partly literally and partly in faithful paraphrase, though I should have liked to put it a little differently. However, by going back (405) we may get the idea. These men of the golden age did not "fill themselves like pools with water and wind, compelling the descendants of Asclepius to give diseases the names of flatulence and catarrh. Is not this a disgrace?"

Socrates is a little off in his citation of Homer, at least the Homer we have, for it is Eurypylus who gets the highball with the kick in it, rather inflammatory, and yet the sons of Asclepius, who were at the Trojan war do not blame the damsel, who gives him a drink, or blame Patroclus, who is treating the case. . . . "Before the time of Herodicus the guild of Asclepius did not practise our present system of medicine, which habituates men to disease (I must alter Jowett's translation a little here). Herodicus, being an educator and himself of a sickly constitution, by a happy combination of training and doctoring found out a way of torturing first and chiefly himself and secondly the rest of the world . . . by the invention of a lingering death. He had a mortal disease . . . passed his entire life as a valetudinarian . . . He was in constant torment whenever he in any way departed from his usual regimen. By the help of science he struggled on to old age."

I have, in the essay on Herodotus, pointed out that our humanitarianism in abandoning the practice of leaving such people to their fate has loaded us and probably our posterity with a burden that may become excessive. We cannot afford to give up our humanitarianism. If we did that we would consider our civilization had perished. Having turned to eugenics as a part of it we are in a quandary how we can let the sick man live and breed. We are nonplussed, too, with the realization that there is very much less than half the truth in the complacent adage, *mens sana in corpore sano*. We know the sick body often harbors a sound mind, at least one often capable of immeasurable benefit to humanity. It was only a little while ago, a generation perhaps, many scientific men were following the demonstrations of Lombroso that genius is akin to insanity. It may be due to the inanity of their lives, but there is as much or more insanity among the children of

the rich than of the poor. If riches after which the best minds are said now to strive are the reward of brains—I do not doubt that, in the broad view, is so—this may strengthen the argument of Lombroso, and it may be erroneous to point to the vapid social life of the modern Croesus. However that may be, constant invalidism has frequently been the life companion of men who have wrought great things not alone in an intellectual and moral way, but in active pursuits. Not only have consumptives and epileptics been great litterateurs, but great soldiers, great philanthropists. The nonsense talked by too many eugenists is overpowering and disgusting. Castration for the poor and concubines for the rich paranoiac have excited but little remonstrance in the public and private discussions of the subject, but no reformer today, any more than Plato in his, can successfully push forward a propaganda so disingenuous. According to their principles Trudeau and Stevenson should have been smothered in their cradles. Napoleon and Cæsar should have been made eunuchs. There is nothing to be gained but the mistrust and misesteem of thinking men by blinking the difficulties of the breeding pen for man. It is singular how this talk of sappy sociologists has been the one optimistic trait which has survived the pessimism to follow an unprecedented slaughter of the healthiest men the civilized world could send to the greatest war that ever was. The world owes as much that is momentous, with exceptions like this, to sick men as to sound, it would seem to those versed in biography.



Tern of Plato in the Vatican.

This was foreign to the Greek way of thinking and Plato could carry out through his spokesman, Socrates, the discussion of a human breeding pen to suit his unrestrained fantasy, but it is much to be doubted if ever any sensible man, much less Plato, believed in its practicality. But if we are going to give free rein to our passionate longings for a better world I am not sure Plato's is not the best that has been painted for us, that is the one which does less violence to our analytical, critical sense. He insists as much on eugenics as the modern eugenist, but neither he nor his successors have solved the problem of the noble lady who loves the squire of low degree. Plato, however, living in an ancient pederastic world where you could do what you pleased with a woman, pen her up in an inner court if you wished, had some excuse of practicality for his sexual arrangements, but you can't pen up modern women with chicken wire. After 2,500 years of experience real eugenics for real men and women in this very real world is further away than ever. I am speaking of eugenics in the strict literal sense of the word without broadening the conception in order to find hiding places for sanity which is doing good work under an unfortunate name.

From the invincible persistence Nature exhibits in breeding as she thinks best one can not but wonder if her plan is not the best after all, but after all, too, what is Nature? The restraints of civilization are a natural product just as much as the child begotten by a genius or a king from a halfwitted family or a washerwoman. Human life as an artificiality in one sense extends far back into the mists of geological ages. Artificiality, the functioning of intellect, even at its start is a natural evolution, but artificiality once begun there is no turning back. Take away the club with which the cave man wooed and won his bride from family and friends, take away the gold with which the soap magnate woos his bride and her family, too, once take away these slightly varying ways of natural selection and the civilizer, the man who sets out to regulate civilization himself, becomes certainly artificial and unnatural if words mean anything, and they often do—anything at all. We have a right to exclaim what a mess the civilizer has made of it! Evolutionary anthropologists declare since the civilizer went to work there has been no progress in man's evolution as an animal, but I fancy this too is entangled in the uncertainty of the definition of words. We may well despair as did Socrates:

"O, dear me, cherished friend, how exceedingly we need rules of the highest excellence, if we are going to breed men, like hunting dogs and the falcons of the chase." He had warned his interlocutors as they approached this problem it was the severest test to which he should put them in helping him with his plan of a republic and we know he was speaking the truth. We are having so much trouble of other kinds with our own it seems hardly worth while to burden ourselves with that. In building an ideal republic only less trouble than in building a real one is experienced, and on the whole there is nothing in Plato's plan which is so demonstrably illusory as his kind of women in common. The ancients did not fully appreciate it but we know it from historical experience and our systematic study of the deepest roots of the psychology of men and women. Indeed in the real world no one has ever thought for a moment of the possibility of erecting a republic on the basis of a community of women, except some partially demented writers in the yellow press about Russia. Kings and aristocrats have been to some extent bred on the plan of Plato's artificial selection

but on the whole there is no time like the present so favorable for finding acquiescence in the conclusion that it has been a failure.

It is scarcely less difficult, for us in our very much more complex and advanced state of civilization it is very much more difficult, to provide by selection for the best in the state in the way of breeding. Even if we knew, it would be an impossible task. Apparently Plato thought he knew what was best and it is symptomatic of the other difficulties with which he must have contended to find he makes Socrates advocate a system of deception and secrecy in carrying out his scheme of making the best breed with the best. Genetics, if it has taught us nothing else, has taught us how uncertain is the result. The discards so vastly outweigh the selections for any special adaptability, indeed for any adaptability at all, to the complexity of our demands for the useful citizen, we may well echo and let the echo magnify a thousand fold the difficulties against which Socrates warned his companions in this matter. I need not allude to the details of the scheme by which he proposed to make headway against them. They are sufficiently well known even to those now very intelligent people who have indirectly what they know of Plato's republic only from the diffusion of the information which has emanated from his genius. The defenders of the state, that is the rulers, were to be chosen from the breeding pen, not by the ballot box. The discards from the breeding pens we can liken rather imperfectly to our defectives and degenerates. These it is said the Spartans destroyed. Plato hides them in places we may presume to liken to our hoped for rather than even now realized asylums, but in his day, before the advent of Christ, anything approaching to these he must have been embarrassed even to imagine.

We look in vain for the modern humanitarianism, which Christ brought into the world, in Socrates as he is drawn by Plato and Xenophon. Still it may be significant of its existence that Socrates does not recommend here the pitiless system attributed to the Spartans, whom Plato and Xenophon so admired. It seems preposterous that pity for human misfortune and suffering and an impulse to ameliorate their condition, quite aside from a regard for the state, should not have been always at least a dormant part of man's nature, buried deep in the inmost recesses of his soul perhaps, but existent at least and not necessarily allied to sentiments of self interest, as Spencerian philosophy insists. The sudden birth of this in the world in the teachings of Christ seems in the ancient world of stoicism something abnormal, so intimately associated with human nature on its emotional side does it seem to us. There was, however, a certain blindness to this side of it in these old fellows of ancient Greece and the stoics they engendered with which modern medicine and especially the modern state is unfamiliar. In the Republic the parturient mother should be allowed to nurse her own child only when there was no wet nurse or changeling to put in its place. It is true this does away at once with the question of illegitimacy and perhaps it solves some other problems, but there seems to us an evidence not of obtunded feelings of human sympathy so much as an obtuseness in an empire builder to a psychology which is fundamental in human nature. Plato looks on thirty years for men and twenty years for women as the most appropriate time for procreation, but he does not enter further into the sexual problem, which, with the decay of the efficiency of religious restraints, is becoming for us so vital a one. This blinking of the human element in Plato's Republic is perhaps its most glaring defect and it was, if tradition runs true, a defect in the man which made him not only absurd in his dealings with the Syracusan tyrants, but nearly made him a slave—a philosopher's ignorance of the heart of man.

So as I read this book of Dupréel's I am reminded that Plato had his limitations, that his generation like other generations stood on the shoulders of its predecessors, but we may also conclude that when men, however learned they may be, lose their historical perspectives they are very apt to start with false premises and come to wrong conclusions. Plato no more than any one else originated in himself. He fed on the wisdom of the nature philosophers. He had more than his share of that nutrition perhaps. We are aware that Plato must have portrayed Socrates after his own heart. We all do that with those who nestle most securely in our own. He doubtless laid in his mouth many things Socrates never said, ascribed to him many thoughts which never entered his head, but for all that, Plato added much that was his own to what he inherited and Socrates was a real figure and he was one to be venerated by after ages if only because he enlisted the love and reverence of a pupil like Plato. He was no myth. He was more than a legend.

Medicine in Jugoslavia.—The last fifty years have seen remarkable progress in the teaching and practice of medicine in some of the associated countries included in the postwar state of Jugoslavia, says the *British Medical Journal* for January 24, 1925. After a long period of lethargy, due to social and political reasons, the national life of Croatia began to awake, and numerous literary and social societies were established between 1860 and 1870. In 1874 the Croat University at Zagreb was founded, and included among its more important scientific societies was the Medical Association of Croatia and Slavonia. For the last fifty years this association has been the centre of medical science in the country, and its activities have given birth to much hygienic legislation and progress in knowledge. The association was from the start the sole representative organization of medical practitioners in the two countries. Various congresses have been held dealing with a large variety of subjects, and in 1877 the official journal of the association, the *Lijecnicki Vjesnik,* appeared for the first time. One of the first aims of the association was the organization of a faculty of medicine at the Croat University of Zagreb—an ideal realized in 1917. In 1923 the association created a body to deal with the many and varied social interests of its members. The jubilee of the association occurred last year.

Contributors to the Science of Medicine

Wilhelm Konrad Röntgen

"Let him who will speak in admiration of the poetic imagination, which soars on spiritual wings in the world of fantasy, singing words that soothe the ear and weaving fancies that stir the emotions. The imagination of the scientist far transcends that of the poet, not only in the scope of its fancy, but surely in concrete accomplishment. . . . In the microcosm, the inspired imagination of Pasteur caused the isolation of a host of organisms, whose destructive and constructive functions are so greatly concerned in medicine. The imagination of Harvey lifted his eyes from the rutted paths over which legions of physicians since the time of Galen had traveled, to a newer vista where lay the truth of the physiological problem of the circulation of the blood So, too, the scientific imagination of Röntgen dared to dream of what was almost scientific heresy, invisible light." This tribute to the great discoverer of the x ray appeared at the time of his death in a biographical sketch by Dr. I. Seth Hirsch, of New York. And indeed the portraits of Röntgen, as well as the comments of his friends and pupils on his personal appearance, suggest that he had many of the personal characteristics which the world has come, rather erroneously, perhaps, to consider as typical of the artist rather than of the scientist. The most striking thing about his face was its revelation of an innate spirituality of nature that gave the warm, kindly glow to his dark eyes, as deep set as those of a musician, the charm of his smile, and the look of the mystic in his countenance when he was engaged upon some abstruse or difficult scientific problem. He was of unusual height, strongly built and robust yet slender, with very dark coloring and a full beard, and finely cut features indicating great refinement and keen intelligence.

WILLIAM KONRAD RÖNTGEN

To his friends and contemporaries, Röntgen was known as the most modest and unworldly of great men. He seemed in no way affected by the honors and acclamations that came to him through his discoveries—he was one of the very few "beginners" who received almost immediate recognition and acclaim—and he never reaped any material benefits from his work. "He gave it to mankind freely and wholly," to quote again from his biographer.

Wilhelm Konrad Röntgen was born on March 27, 1845, at Lennep in Eastern Prussia. His father wished him to follow in his footsteps, so sent him to a school of engineering in Holland to study th science of agriculture. Here he had his first scien tific training, going later to Zürich where he entere the polytechnic school. The famous physicist Clausius, was at that time teaching in the school, an it was doubtless in his classes that the young Rön gen heard first the principles of the dissipation o energy and the mechanical theory of heat produc tion. He was graduated from the university with degree of doctor of philosophy, and, what was eve more worth while, with a reputation for being fit i an unusual degree to do scientific work with ability accuracy and industry. Because of this he was mad assistant to Kundt, with whom he was associated i teaching for a number of years, and to whom he de clared he owed his best train ing in exactness of investiga tion. In 1870 Kundt wa summoned to Würzburg an Röntgen went with him, fol lowing him a few years late to Strassburg, where he wa made lecturer in physics After various other changes each a step higher in his pro fession of physicist, Röntge was finally called in 1888 t the directorship of the insti tute of physics in the univer sity of Würzburg, the secon most important university i Bavaria. It was here that th great discovery of the x ra was made.

Dr. Hirsch describes th discovery in a very tellin way:

"It is late in the fall o 1893. The ancient town o Würzburg is basking in th autumn sunlight in the vine clad valley of the Main. I the broad and tree line Pletcher-Ring is the Institute of Physics. Withi its walls, in a room littered with scientific appa atus, a man stands deep in thought before a glas bulb glowing with colored light. . . . Th little glass tube he studies so intently as it glow and flickers with its iridescent hues—what an amou of thought, of painstaking, laborious investigation represents! Pluecker, Gassiot, Geissler, Hittor Varley, Crookes, and Lenard, and before them a Faraday—how persistently the human spirit strive to find the meaning of Nature's mysteries! How crude the beginning, how halting the progress, ho hidden the goal! How slowly the foundations ar laid, often without definite plan; the walls risin haphazard, isolated, disconnected, until the maste mind sets the cupola, and lo! the structure glow with a beauty and significance undreamed of.

this vacuum tube, energized by the current of an induction coil, lie many of the mysteries and marvels, not only of modern electricity, but of matter itself—its ultimate constitution—the master problem of the universe. Geissler had passed the induced current through a tube of low vacuum and had produced the exquisite color effects. Hittorf had discovered the cathode ray therein. Crookes noted the change in the phenomena, as the vacuum was increased to about one millionth of an atmosphere. On Hertz's suggestion Lenard brought the cathode stream out of the tube, and studied it exhaustively. All this was in the mind of Wilhelm Konrad Röntgen, then professor of physics at the University of Würzburg, as he watched the flickering bulb. He noted the beautiful green fluorescence of the glass tube, just as Pluecker had done thirty-five years ago, and thought of Crookes's designation of 'radiant matter' as that influence which apparently radiated from the negative pole." The account is continued of how, called from the room, he laid the still glowing bulb on a book he had been reading that morning, and in which lay a large, flat antique key, which the great scientist was in the habit of using for a bookmark. It happened that just under the book lay a photographic plate holder, filled to use on an outing that afternoon. This plate was to give later the fateful exposure that has meant such countless things to science. When it was developed, the shadow of the great, antique key appeared on the negative. To a scientific mind like Röntgen's such a phenomenon demanded a scientific explanation, and he proceeded to analyze it. He first repeated the procedure that had led to the photograph, with identical results. Next he placed his hand over a covered photographic plate, energized the Crookes's tube above, and there was a photograph of the shadow of the bones. From these meagre but most significant beginnings, he carried on his researches until convinced that he had found a new form of radiation. Then, in 1895, he reported his results to the Würzburg Physicomedical Society, and in 1896 in a paper entitled A New Form of Radiation.

After this many honors were heaped upon him and many high positions offered him. The title of Excellence was bestowed upon him by the German government, and his statue was erected in Berlin. In 1901 he received the first Nobel prize for physics.

Like so many of the great-minded Germans of our times, the World War came as a calamity to his life, and in fact broke it. His grief was so deep that it affected his health, and his last illness and death were aggravated by the poverty and depressing conditions under which he had to live during the last few years of his life. He wrote to a friend at this time, "In deep grief our hearts ask what is to be the future of this people, and how will they ever reestablish themselves? It indeed requires the greatest courage and faith to walk unbowed in these days."

Death came to him on February 10, 1923, when, in spite of poor health, great poverty and depression of mind and spirit, he was still filling his place as professor of experimental physics in the University of Munich.

John Stearne, Founder of the Irish College of Physicians

The three hundredth anniversary of the birth of John Stearne (1629-1669) was celebrated by a reception on November 26th by the Royal College of Physicians of Ireland says the *British Medical Journal* for January 24, 1925. A scholarly address of great literary distinction, dealing with their pious founder's life and activities was delivered by the registrar, Dr. Percy C. Kirkpatrick, whose numerous essays on the same lines mark him as the author to provide us with a complete history of the Irish College of Physicians.

Stearne entered Trinity College at the tender age of fourteen and one half years, and became a scholar in 1641; but the times became so troublous that the Provost sought refuge in England, and among others Stearne followed his example; in 1642 he entered Sidney Sussex College, Cambridge, where he almost immediately took the B.A. degree, proceeding to the M.A. in 1646; in the intervening four years, the happiest part of his life, he probably read deeply in classics, the philosophical works of the ancient fathers of the Church, and medicine. Francis Glisson was regius professor of physics (1637-1677); Wharton of Pembroke and the *Adenographia* and George Ent of his own college were then associated with the university. About 1649 the times again obliged him to move, and on this occasion he went to Oxford, where he turned in his distress first to stoic philosophy and then to peace in Bedfordshire. But in 1651 he was admitted a Fellow of Trinity College, Dublin, becoming a Senior Fellow in the next year and professor of Hebrew in 1656; as he was also professor of medicine and perhaps lectured on law, he is a typical example of the all round excellence of a Fellow of Trinity. His seventeen years of residence were extremely busy and saw much productive work; he wrote six books in Latin, all on philosophicotheological subjects and not dealing primarily with medicine; his erudition was great, but originality—in those days a dangerous property—was not obvious in his writings.

As a medical practitioner, Stearne was a follower of Hippocrates rather than of Galen, being an ardent supporter of physical therapeutics, and an enthusiastic advocate of the use of cold water, tobacco (chiefly by chewing), opium, and the smell of freshly dug earth, which, Dr. Kirkpatrick slyly adds, may also "explain the benefit which some golfers believe that they obtain from the pursuit of the game." In 1661 Stearne set about founding the College of Physicians, obtaining a Royal Charter from Charles II in 1667, and was nominated president for life.

Editorial Articles

MILLIONAIRES AND MEDICINE

Whatever may be the feelings of American millionaires, and many are ascribed to them, a lack of generosity to science and medical science cannot be laid to their charge. Indeed, in the cause of education of every description they have poured out money like water. Unlike the very rich men of other countries, or rather in a greater degree than the rich men of other countries, they have had the shrewdness to perceive that money spent in the interests of medical science will be returned manifold. Their reasoning is eminently logical. If a country is not healthy and well educated it cannot be prosperous and must quickly decline; and in a poor country what opportunity is there to amass fortunes?

Health comes before all. Sickly or ill nurtured persons, however well educated, cannot compete successfully with healthy and vigorous well educated persons. Therefore, first make the individual members of a nation healthy and then equip them at all points, according to their several bents, for the battle of life. The rich men of this country have recognized that it is to their own advantage that their fellow citizens shall be healthy and thoroughly educated, and have expended money without stint in order that this aim as far as humanly possible shall become a fact. It may be said with truth that the dollars of the multimillionaires are leading the attack against two of the traditional and most to be dreaded enemies of the human race, ignorance and disease, which go hand in hand. In the battle against disease stupendous sums have been and are being spent. A short time ago James B. Duke of tobacco fame gave forty million dollars to found a college and to aid charities, especially hospitals.

Of course, the Rockefellers have contributed most largely to medical science and to the discovery of means for preventing disease. For example, the Rockefeller Institute and various other foundations have given millions for the furthering of medical research and the elevation of medical standards in all parts of the world. Remarkable results have been obtained already and the work of the scientists of worldwide renown connected with the foundation are really public, almost international, property, and in their field have done immeasurable good. Many other millionaires have made hospitals and research institutions their chief means to aid the public in the fight against disease, and the money totals given run into the hundreds of millions. Moreover, these amounts are not spent but merely the income from them and thus the total will continue to increase. Millionaires and medicine in this country are linked together in the campaign against disease for the good of humanity, the nation and the individual.

NUTRITION AND THE TEETH

Any one who has had occasion to observe the teeth of animals must have been struck with the fact that they are not decayed. A dog may get so old that his teeth are worn down, and he may have broken some of them off, but a dog with dental caries is rare indeed.

Paleontologists have long recognized the fact that primitive man did not have defective teeth. Even the Nebraska tooth, from which the Hesperopitecus has been reconstructed, showed no cavity formation and in the hundreds of precolumbian skulls in the National Museum at Washington there is scarcely one which shows any evidence of dental decay. It is a sad commentary on our civilization that from fifty to seventy-five per cent. of the school children in the United States have defective teeth and that this condition is the result of our civilization is shown by the fact that primitive man, who ate a relatively well balanced ration, had no such defects. Mound builders' skulls frequently show the teeth ground down more than half on account of the diet of parched corn which they ate, while modern skulls, taken from a burial place only a few hundred feet away, show evidences of extensive decay and little wear. The one wore his teeth out; the other rots them out.

The large amount of tubers and cereals which we have introduced into our diet and above all, the terrific quantity of sugar which we consume, are reducing man to a creature with a poor masticatory apparatus.

There is a more serious phase of the question than this. This incomplete, lopsided diet is producing skeletal defects and is reducing the physical stamina of the race. We are eating degerminated cereals when we should be eating meats, and we are consuming canned vegetables which have had some of their vitamines killed when we should be eating fresh green vegetables. A considerable portion of the race is therefore suffering from an avitaminosis. When the results of a badly balanced diet produce rickets, or scurvy, or beriberi, or pellagra, the condition is easily recognized and given appropriate treatment, but there are hundreds of

cases of subnormal health which are due to a lack of the vitamines in the diet which do not receive the appropriate dietary regimen.

Practising physicians should pay more attention to what their patients are eating and they should endeavor to indocrinate them to the end that they will eat more of the proteins and less of the foods which are lacking in vital elements. Above all, they should teach the danger of the excessive use of sweets and sweet foods and they should see to it that the person of sedentary occupation does not consume a dietary which would be suitable for a farm laborer. Here is a thing on which the integrity of the race depends and man must cease to starve his body in this way, or a rapid and continuous degeneration of the racial stock will surely follow.

THE PREVENTION OF HEART DISEASE

Many, perhaps most, of our diseases, are diseases of civilization. Of all the diseases which have progressed *pari passu* with civilization heart disease, on the whole, is the most prominent, inflicting the largest amount of disability, and taking the greatest toll of human life. In Great Britain heart disease heads the list as the cause of death and in this country its advance has been so alarming that a strenuous campaign has been instituted against it throughout the land.

Eight cardiac associations have been formed and cardiac clinics have been organized in fourteen States or twenty-three cities in this country and two in Canada. In addition, in May, 1922, at a meeting held in St. Louis, called together at the invitation of the Association for the Prevention and Relief of Heart Disease of New York City, it was decided to form a national committee. A meeting of this committee was held at Atlantic City May 1, 1923, when it was resolved to incorporate the American Association for the Control of Heart Disease, to be based at the outset on the local cardiac organizations of the various cities.

It will thus be observed that the danger of existing conditions is realized by the medical profession here and that steps are being taken to control the advance of heart disease. Dr. B. L. Russell has contributed a series of articles to the *Boston Medical and Surgical Journal* on the medicosocial aspects of heart disease. In the concluding article in that journal of October 9th, it is pointed out that the prevention of heart disease is by far the most important measure to be considered in putting forward an effective program for the campaign against cardiac disease.

Attention is drawn to the fact, that the early recognition of rheumatic, syphilitic and thyroid conditions are essential steps in eradicating heart disease, but one of the most important measures is the eventual prevention of such diseases as rheumatic fever, chorea, and syphilis themselves.

In a valuable report on the incidence of rheumatic diseases in England and Wales compiled by insurance practitioners in various parts of that country and revised by specialists attached to the British Ministry of Health, and published by the Ministry in the early part of last year, the relationship between heart disease and rheumatic affections is traced and commented on. It is stated that nearly half the patients treated for acute rheumatism showed signs of recent or old endocarditis. It must also be taken into account that chronic heart disease is probably largely rheumatic in origin. Thus, it seems that in England and Wales rheumatic affections are responsible for a large proportion of the heart disease and in this country conditions are more or less similar. Of course, too, syphilis is a cause of a considerable amount of heart disease, and so are thyroid conditions to a lesser extent.

Therefore when Dr. Russell says that the most rational and certain means of exterminating or of greatly limiting the occurrence of heart disease is by preventing rheumatic fever, syphilis and thyroid conditions, an obviously sane and reasonable statement is made.

In many laboratories, and notably in those of the Rockefeller Foundation, efforts are being made to discover the organism which causes rheumatic fever. Dr. Russell points out that better coordination of the medical departments in industrial plants with services available through family physicians and hospital clinics, would greatly aid in the recognition and treatment of early syphilis and abnormal thyroid conditions.

The situation, stated briefly, appears to be that rheumatic affections, syphilis, and abnormal thyroid conditions are mainly responsible for the menace of heart disease and that the only really effective way of grappling successfully with the problem is to prevent these diseases and conditions as far as is possible. Among the many ways in which rheumatism may be prevented is the insurance, as far as may be, of a sufficient supply of good houses and, as far as can be done, an adequate provision of suitable food. Care of the teeth and tonsils is another mode of prevention.

Dr. Russell says a closer cooperation must be sought with industry, that is, in order to prevent heart disease and heart failure more frequent medical examinations must be made and closer medical supervision instituted. Educational propaganda is indicated to teach the masses and the young that heart disease may be largely prevented and con-

trolled by preventing diseases which by poisoning and devitalizing the system provide a fruitful soil for the germination and development of the seeds of infection.

THE COMPLICATIONS OF SYPHILITIC PANCARDITIS

There are three lesions in syphilitic pancarditis which, in reality, are true complications of the specific gummatous, sclerous or vascular changes. These are aneurysm of the heart, infarct, and rupture of the heart.

Portal, in the eighteenth century, had already pointed out that the virus of syphilis might produce erosion of the heart, with consequent weakening of its walls. Later on, Kockel related the case of a man with long standing lues who died in asystolia. At autopsy a sclerous myocarditis was found with a partial aneurysm, the size of a pea, at the apex of the ventricle. There was also a fluid collection in the pericardium which was partially adherent. There were sclerogummatous lesions in the myocardium, while the endocardium was thickened and fibrous.

The cases recently reported by Pick and Bouisson, Caussade and Joltrain may be mentioned. It can readily be conceived how, following the elimination of a completely softened gumma, the cardiac muscle may be so thinned as a result, that it allows itself to be forced and partially dilated. Whether there is a large infarct or a cicatricial sclerosis there is always partial destruction of the walls which may result in aneurysm.

Infarct of the myocardium occurs especially after a specific involvement of a branch of the coronary. A complete occlusion of the arteriole ensues and, as a consequence a local apoplexy—a zone of congestion —which will characterize the infarct. Salles has recently recorded a detailed description of a case in his thesis (Paris, 1918), and some years ago Ehrlich also reported an instance.

Although an aneurysm may not have necessarily resulted from mere thinness of the cardiac walls determined by miliary gummata or foci of sclerosis, rupture of the heart may ensue spontaneously. Turner has reported rupture of the aorta into the pericardium and a similar case has been recorded by Nitot. Kroenig found in an old syphilitic a voluminous hemopericardium and atrophy of the fibroid wall of the ventricle to the extent of two millimetres thickness, presenting a parietal thrombus. The case reported by Deguy and Ménard was that of a man of twenty, who suddenly died. A subepicardiac infarct was found with rupture of the left ventricle.

The treponema leaves traces in the heart walls in the form of disseminated lesions. Those of the interauriculoventricular septum, involving the bundle of His, give rise to the Stokes-Adams syndrome. The muscular fibres composing this bundle may be the seat of gummata, diffuse embryonal lesions or a more or less circumscribed fibrous myocarditis. At least this is Vaquez's opinion. To this pathology, Bricout adds the possibility of extension of a chronic syphilitic aortitis to the bundle of His. Quite a few instances of gummata of the septum have been recorded by Rendu, Breitmann, Stockmann, Hanford, Chapman, Robinson, Stork and Handwerk. Vaquez and Esmein have described the sclerogummatous changes of the bundle of His, which is infiltrated with minute patches of sclerosis. Similar cases have been observed by Ashton, Norris and Levenson.

Finally, the bundle of His may undergo purely fibrous changes. The lesion is manifest, but its syphilitic origin, although suspected, cannot be absolutely demonstrated.

ON PHARMACOLOGICAL HEART CONTROL

There are certain drugs which have been shown to have a definite action in controlling the heart and as such are used with effect in suitable cases. Opinions as to the value of some of these drugs differ and even in the case of the most widely used and greatly lauded heart drug of all, digitalis, views are by no means unanimous and by some digitalis is regarded as not wholly worthy of the praise which has been so long and so heartily lavished upon it.

In an especially able paper by one of the first British authorities which Dr. Alexander Blackhall-Morison read before the North London Medico-Chirurgical Society on December 20th last and published in the *Medical Press and Circular,* March 5, 1924, the subject of heart control is dealt with. That part of the paper which discusses the pharmacological treatment of lost heart control is well worthy of a close study. The author rightly says that pharmacologically we have to sit at the feet of Nature, and some of the most potent instruments of pharmacological heart control have been empirically discovered by the laity, before they were scientifically studied and recognized by the profession. It is pointed out that the drugs used to obtain and promote control when it is lost, in the case of the heart, fall into three groups, like the elements of the triple unit, namely:

1. The digitalis group. 2. The atropine group among which may be classed those agents which relieve pain, induce sleep, and affect the vasomotor system, such as neural hypnotics and the nitrites. That supremely valuable agent opium belongs, however, most reasonably to the digi-

lis group. 3. The hematinic group. In other ords, the pharmacological agents which enble us to control the disordered heart are those hich retard its action, those which accelerate or ugment it and those which promote the nutrition f the organ. Digitalis the "opium of the heart," as has been called, belladonna, the rouser, the ccelerator, augmenter of the heart, and the poppy, ne soother of the nervous system, are types of the eneficial agents without which the cardiologist ould exercise little control of the heart.

Blackhall-Morison compares the effects of digilis and quinidine in auricular fibrillation and oints out that it is a peculiar but undeniable fact iat cases of irregular action which have resisted ie effects of digitalis for years, become quite regur in some cases, under quinidine in a few days. Moreover, that when such cases relapse, they again romptly take on a regular action on the resumption f quinidine. The explanation given is that probbly the rationale of the action of digitalis and uinidine is not the same.

There is good evidence that digitalis acts as an hibitant of cardiac action through the vagus, while uinidine is believed to act directly on cardiac uscle. Blackhall-Morison has never observed reardation with rhythmical extrasystole after the se of quinidine, as is often seen after digitalis. Of ie value of mercury as an adjuvant in the pharmalogical control of the heart, clinical experience aves no doubt. The writer thinks that it may aid ie action of digitalis and squill by intestinal disinction, although the clinical result best established a reduction of blood pressure in arteriosclerolc cases, and the promotion thus at times of profuse iuresis and easier heart action. To the value of ie endocrines in cardiotherapy Blackhall-Morison fers with caution but praises both camphor and rychnine as effective heart stimulants. In most ises of heart disease or of loss of heart control or defective heart control drugs are valuable, indeed sential. There are those who will hold that drugs e of little avail and that the main reliance in the ajority of cases of heart affections should be aced on rest and diet, on posture and exercise id so on.

But clinical experience goes to show that drugs ed judiciously and as adjuvants are of great use treatment, in certain cases essential to success. rug nihilism is not so prevalent as a few years ago. t one time, perhaps, the value of drugs was exgerated, and fads with regard to an especial drug nded to become established to the detriment of l concerned. Now common sense views with reird to drug therapy are the rule, and as Blackhallorison shows, clinical experience even if not altogether always in keeping with modern views must carry weight. A good deal of old fashioned drug therapy if empirical was based on some clinical experience and is returning into vogue, together with views as to etiology which were supposed to be dead.

THE CHILD GUIDANCE CLINIC FOR THE PROBLEM CHILD

"A child guidance clinic is an organization that seeks to bring to the study, training and treatment of problem children whatever medicine, psychiatry, psychology, education and social case work offer. These contributions from specialists in different fields are combined in a well rounded, coordinated unit, known as a child guidance clinic, that seeks to deal, not only with the child, but with situations in his environment that have contributed to make him what he is. In a child guidance clinic, no part of the study—physical, psychiatric, psychological, educational, or social—is separate and distinct unto itself. Each goes to make up a total and complete picture of the individual child and his adjustments to life. They each contribute to a properly rounded program of rehabilitation and treatment." Thus Dr. V. V. Anderson, director of the Division for the Prevention of Delinquency of the National Committee for Mental Hygiene, defines and describes the function of the child guidance clinic in an article in the October, 1924, number of the *Nation's Health*. Dr. Anderson develops his subject in a practical and satisfying manner by asking pertinent questions, then giving brief but adequate answers to them. These questions include discussion of the personnel of such a clinic, its cost, how it should be financed, the type of child that should receive the services of such a clinic, what is a social examination, why is a physical examination made, what is a psychological and what a psychiatric examination, how does the clinic make use of this information for the benefit of the child and those responsible for his guidance, is the cooperation of various local agencies important in treatment, how can a community be made acquainted with the significance of such a movement and the existence of such an enterprise, and how can a city secure aid in developing a child guidance clinic along the most modern and approved lines. Important as are all these questions, perhaps the last is the one which communities know least how to answer or even get information about. Dr. Anderson goes on to tell us that a special division within the National Committee for Mental Hygiene has been created for the purpose of administering that phase of the Commonwealth Fund's program, which is concerned with psychiatric, or child guidance, clinics. This division, un-

der Dr. Anderson's direction, maintains for cities interested in the development of psychiatric and child guidance clinics two types of clinical service: demonstration clinics, and consulting field service.

The Demonstration Clinic Service maintains two large clinics, staffed by psychiatrists, psychologists, psychiatric social workers, and statistical and clerical forces. These clinics remain approximately one year in a community, then move to another demonstration centre, and are available only to the largest cities where the best social facilities may be utilized in conducting a model demonstration. "The object is to plant only a few demonstration centres in the country—hoping to develop in these centres a type of work that will stand out as an object lesson to other cities." One of the conditions of obtaining the services of these clinics is that the period of demonstration in the city shall be followed by a permanent clinic locally financed. Such clinics must be adequately maintained, with a minimum annual budget of at least twenty-five thousand dollars. Properly trained personnel must be secured and close relationship with various local agencies maintained. "It is expected that the director of the permanent clinic shall have some relationship to the teaching faculty of the university in cities chosen."

These demonstration clinics not only demonstrate the methods employed in the adjustment of problem children, but also concern themselves with organizing the facilities of the community for working properly in cooperation with the permanent clinic. The demonstration staff works with the division's central office in the choice and training of personnel for the permanent clinic.

The Consulting Field Service, the second type of clinical service rendered, is available to cities, large and small, that are not able to receive the larger demonstrations, yet wish to develop their own clinics and to have assistance and advice as to organization and operation. The consulting field staff remains usually three or four months in a city, helping in assembling the personnel, getting under way the work of the clinic, perfecting its organization, establishing its relationship to the community, laying down sound clinical and social case methods, and "carefully nurturing along the most approved lines the undertaking until it has achieved a safe development." No city is eligible for receiving such service which is not already prepared to finance some sort of clinical work and is seeking aid in establishing it. A minimum budget of fifteen thousand dollars is considered necessary for child guidance clinics in smaller cities.

Dr. Anderson believes that a community can best be made acquainted with the significance of such a movement and the existence of such an enterprise through the appointment of a child guidance advisory committee in each city. This committee should be made up of influential persons from the various official and public agencies of the community, and should make a study of the need for such a clinic and develop a program in which all the social facilities of the city play a part. This committee "should carry on a constant stream of education before various clubs and organizations. When the child guidance clinic has been established, this committee should become the advisory and administrative group in charge of the enterprise. It should through its continuing study of the needs of the clinic and the community, seek to develop the work along the soundest and safest lines."

News Items.

Army Medical School.—Graduation exercises of the Army Medical School, the Army Veterinary School, and the Army Dental School were held February 10th, in Washington.

Memorial Meeting.—A memorial meeting for the late Dr. Walter E. Fernald, first president of the Massachusetts Psychiatric Society, was recently held at the Boston Psychopathic Hospital.

Nome Diphtheria Epidemic.—Reports from Nome that the diphtheria epidemic is under control and no further antitoxin needed at present, have resulted in the cancellation of the flight of the navy plane.

Memorial to Dr. Dyer.—A bronze portrait panel of the late Dr. Isadore Dyer, for many years dean of the medical school of Tulane University of Louisiana, has been erected by the faculty, and recently dedicated. The address was made by Dr. Rudolph Matas.

Georgetown Research Laboratory.—A research laboratory, to be known as the Institute of Chemical-Medical Research, is to be established at Georgetown University, Washington, D. C., supported by an initial endowment of five million dollars, to be in hand by next December.

Psychiatry Fellowships.—Fellowships for training in psychiatry have been granted to Dr. Paul J. Ewerhardt, formerly of the Kankakee and Chicago State Hospitals, and to Dr. Philip J. Trentzsch, formerly of St. Elizabeth's Hospital, Washington. Study for the present will be done at the Boston Psychopathic Hospital.

Memorial to Dr. Andrew J. McCosh.—Among the gifts to the new Medical Centre is a donation of $100,000, by friends of the late Dr. Andrew J. McCosh, for an operating amphitheatre. An additional $93,000 will be used to establish a memorial fund to further medical and surgical knowledge, under direction of the board of managers of the Presbyterian Hospital.

Physicians in Industry.—The forty-sixth meeting of the Conference Board of Physicians in Industry was recently held in New York. Discussion was devoted to the care of trifling injuries, for the avoidance of infection, and treatment of more serious cases drawing compensation benefits, with the return of the worker to some sort of employment under supervision, as soon as possible.

Contest Winners.—The essay contest on "Interrelationships of Hospital and Community," held by the *Modern Hospital*, resulted in the awarding of the first prize of $350 to Mr. Edward A. Fitzpatrick, dean of the graduate college and educational director of the hospital college of Marquette University, Milwaukee; the second prize of $150 to Dr. Lucius R. Wilson, assistant superintendent of Barnes Hospital, St. Louis; and the third prize of $100 to Dr. D. L. Richardson, superintendent of City Hospital, Providence.

St. Louis Medical Society.—The St. Louis Medical Society is beginning its new building, the library portion being constructed first. An expenditure of about $300,000 is contemplated.

Supervision of Baby Shows.—A resolution of the council of the Illinois State Medical Society suggests that all baby shows or baby conferences held in the state should be under the general supervision of the state society, and the direct supervision of the county society.

New Germicide.—A new antiseptic, named hexylresorcinol, to be taken internally for disinfection of the kidneys and urinary tract, has been developed at Johns Hopkins University, by Dr. Veader Leonard, chairman of the clinical committee on internal antisepsis of the National Research Council. The council has appointed a committee of fifteen to work with him in further researches to determine the extent of the application of the chemical.

Postgraduate Study.—The seventh annual postgraduate course in infectious diseases and public health, offered through Albany Medical College and the New York State Department of Health, will begin March 5th. The fee is twenty-five dollars, and the courses will be of interest both to practicing physicians and to health officers. Communications should be addressed to the director, Dr. Charles C. Duryee, State Department of Health, Albany, New York.

National Board Certificates.—The State Boards of Medical Examiners of Michigan, Oklahoma, and Wyoming have recently passed resolutions authorizing the acceptance of the certificate of the National Board of Medical Examiners for medical licensure. Michigan reserves the privilege of reviewing the full credentials of each candidate, and in Wyoming, an oral examination will be given. There are now thirty-one States accepting the National Board's credentials.

Gifts and Bequests.—Among the public bequests in the will of the late Emily Howland Bourne was included $10,000 to the New York Eye and Ear Infirmary, and $20,000 to the New York Association for the Blind.

The will of the late Mrs. Kate S. Richardson provides $200,000 for the New York Hospital, $100,000 for the United Hospital Fund, $200,000 for the Henry Street Settlement, and $60,000 for the Association for the Aid of Crippled Children.

Chiropractic Licensing.—A bill introduced before the New York Legislature requires that chiropractors have sufficient knowledge of studies generally pursued by medical students to enable them to diagnose disease. The bill also provides that one chiropractor shall be a member of the board examining and licensing all practitioners; that chiropractors in practice ten years can be recognized without prior examination, and these would have to have graduated from a two years' course of four months each.

Friends of Medical Progress.—The society known as Friends of Medical Progress, with headquarters in Boston, has moved to New York, 370 Seventh Avenue, where there will be more opportunity for cooperation with other health organizations. The name has been changed to American Association for Medical Progress, and Mr. Benjamin C. Gruenberg will be in active management. The purpose of the organization is the dissemination of medical knowledge among the general public.

Dental Hygiene Lecturers for Medical Societies.—The Oral Hygiene Committee of the State Dental Society offers cooperation with the Division of Maternity, Infancy and Child Hygiene in providing dentists to lecture before medical societies on the care of the teeth of the preschool child and the expectant mother. Requests for this service may be sent to the Division of Maternity, Infancy and Child Hygiene, or to Dr. Lincoln A. Timerman, 39 Market Street, Amsterdam, N. Y., chairman of the above mentioned committee.

Postgraduate Tour and Clinic.—A foreign tour, lasting from May 18th to July 6th, has been arranged by the Interstate Postgraduate Assembly of America. Clinics will be held in Toronto and Montreal, and also in London, Liverpool, Manchester, Leeds, Dublin, Belfast, Glasgow, Edinburg, Newcastle, Paris, Lyon, and Strasbourg. Extension tours may also be arranged for other cities. The tour is open to members of the profession in good standing in their state or provincial societies, and to their families. Correspondence should be addressed to Dr. William B. Peck, Managing Director, Freeport, Illinois.

Personal.—Dr. William Allen Pusey, president of the American Medical Association, and a charter member of the Chicago Dermatological Society, was the guest of honor at its twenty-fifth anniversary meeting.

Dr. Irvine McQuarrie has become chief of the newly organized pediatric service of the Henry Ford Hospital, Detroit, resigning from his position at Yale University.

Dr. Archibald S. Dean, who has served as psychiatrist on the staff of the National Committee for Mental Hygiene, has been appointed pediatrist in the Division of Maternity, Infancy, and Child Hygiene of the New York State Department of Health.

Dr. Ralph P. Truitt, formerly medical director of the Illinois Society of Mental Hygiene, and also director of the National Committee for Mental Hygiene's child guidance clinic in Los Angeles, has been appointed director of the division on the prevention of delinquency of the committee.

Dr. Curran Pope, neurologist, of Louisville, Kentucky, has been appointed to the State Board of Charities and Corrections.

Hospital News.—Unity Hospital of New York has opened its newly equipped clinic and outpatient departments. Free insulin and radium can be provided for needy cases.

The Brooklyn Jewish Hospital is planning the construction of a new wing, to cost $600,000.

On September 1st the municipal hospital at Montebello, Baltimore, will open six buildings, forming the nucleus of the Baltimore General Hospital. The amount expended has been about $900,000. Dr. Birkhead MacGowan will be superintendent. Treatment will be free to residents of Baltimore.

Ten social workers have been added to the staff of the St. Louis city hospitals, by a recent authorization of the board of aldermen.

The Woman's Homeopathic Hospital of Philadelphia is starting a new building, to be known as the Emma Shaperkotter Maternity Wing, which will cost about $250,000.

An eight-story brick building, to cost $110,000, is planned for the Bekur Cholim Hospitar, Lafayette and Summer avenues, Brooklyn.

The Polyclinic Hospital of Harrisburg, Pennsylvania, will soon begin work on a $300,000 building.

Seven lots on East Ninety-eighth Street, New York, have been contributed to Mount Sinai Hospital by its trustees, to provide space for a maternity hospital, psychiatric clinic, and school of nursing.

Society News.—The Bronx Dermatological Society, of New York, has recently been founded, for the clinical study of dermatology, with Dr. Adolph Rostenberg, president, and Dr. M. Breakstone, secretary.

Tentative plans have been made for the fifteenth annual meeting of the American Psychopathological Association, to be held in Washington, May 7th or 8th.

The ninth annual clinical session of the American Congress on Internal Medicine will be held in Washington, March 9th to 14th. Practitioners and laboratory workers interested in the progress of scientific, clinical, and research medicine are invited to take advantage of the sessions; inquiries should be addressed to the secretary-general, Dr. Frank Smithes, 1002 North Dearborn Street, Chicago, Illinois.

At the meeting of the Washington Heights Medical Society, January 13th, at the parish house of the Chapel of the Intercession, installation of the following officers took place: President, Dr. W. H. Boese; first vice-president, Dr. L. L. Fulkerson; second vice-president, Dr. Gove S. Harrington; treasurer, Dr. Winifred Perkins; secretary, Dr. William A. Fraser; membership committee, Dr. Frederick E. Bauer, Dr. W. W. Bostwick, Dr. Harold W. Brown; literary committee, Dr. Robert H. Rose, Dr. Franklyn Welker, Dr. Alexander Nicoll.

The New York Physicians' Mutual Aid Association held its fifty-sixth annual meeting on Tuesday, January 27, 1925, at the New York Academy of Medicine, in which building the Association has had its office for many years. The membership now stands at about 2,300, distributed throughout and confined to the State of New York. The management of the organization is in the hands of a board of trustees, all of whom are physicians and who serve without remuneration. Among the officers elected for 1925 are Dr. Ward B. Hoag, president; Dr. A. Edward Davis, secretary; Dr. Howard Gillepsie Myers, treasurer.

Foreign Correspondence.

LONDON LETTER

(From our own correspondent)

London, *January 3, 1925.*

SMOKE AND HEALTH

The serious effects on public health of the pollution of the atmosphere by smoke, and the special culpability of the domestic open fire, were the subjects for comment in the annual report of Dr. R. King Brown, Medical Officer of Health for Bermondsey, London. He asserted that smoke pollution was one of the most urgent problems of public health, and with the growth of urban areas it became increasingly important. That respiratory diseases, including pulmonary tuberculosis, were greatly aggravated by the condition of the atmosphere was universally admitted. He pointed out that here in London the death rate from these diseases mounted up during and immediately after a fog, so that there could be no question of a connection between the two. The problem was very complicated, especially as three fourths of the smoke was caused by domestic chimneys, and more than three fourths of the damage. In the case of industrial smoke, the combustion being done in high temperature furnaces, was more complete and there was an absence of tar and acid products, whereas in domestic smoke, caused by the combustion of ordinary coal at a low temperature, there was a very large proportion of tar and acids, which were the chief causes of the damage, not only to the buildings but to people's lungs. It was thus evident that the stopping of industrial smoke, though it would help matters considerably, did not by any means solve the problem of the pollution of the atmosphere, since it left the domestic problem untouched. As a matter of fact the problem was mainly an economic one. Until a cheap smokeless fuel equal in efficiency and price to ordinary coal, was placed on the market, there seemed little chance of doing away completely with the domestic coal fire. Of late years there had been a great increase in the use of gas and electricity in London, and the improvement produced thereby was noticeable in the diminution of the severe fogs which used to occur regularly about November some twenty-five years ago. There was no doubt that this pointed the way to reform in the matter of domestic smoke, and every endeavor should be made to encourage the use of gas and electricity for cooking and heating, and at the same time to discourage the use of raw coal for the same purposes. British people seemed to be wedded to the ordinary open fire, and until a plentiful supply of cheap smokeless fuel was discovered Dr. Brown did not think that there was any chance of clearing the atmosphere.

LONDON HOSPITALS

The Prince of Wales presided recently at a meeting of the General Council of King Edward's Hospital Fund for London, held in St. James Palace, when grants aggregating £235,000 were awarded to the various London hospitals and to convalescent homes, not attached to these institutions. In addition, distributions amounting to £81,000 were authorized out of the legacies of the late Mr. and Mrs. Wells in aid of extensions and improvements, making a total for the year of £316,000. In his speech the chairman described the improvement in the finances of the hospitals as "almost miraculous." It meant, he said, that the people of England were really attached to the voluntary hospitals and were ready to make the necessary sacrifices to maintain them. He announced that it had been decided to extend the area of the fund's operations from a radius of nine miles round Charing Cross to a radius of eleven miles round St. Paul's, thus bringing in more of the eastern districts.

On December 17th last Mr. Neville Chamberlain, Minister of Health, was the principal speaker of the Mansion House, London, at a largely attended meeting of the constituents of the Metropolitan Hospital Sunday Fund. Mr. Chamberlain said in part, that in spite of the wonderful generosity of the public, the voluntary hospitals were still struggling against circumstances which were almost too much for them in trying to maintain their services at the level at which they desired to see them. The expenses of administration had increased enormously. If the hospitals were to maintain themselves up to date; if they were to take advantage of recent developments, and be able to give to those who attended them the very latest types of treatment, with the very best equipment, then it would inevitably mean that the cost of a bed must continue to rise, and the demands on the public become greater and greater. If the voluntary system were to break down, if some day in the future voluntary hospitals had to be taken over by local authorities or by the State, he imagined that their disappearance as they stood today would leave a gap in the social system which they would find difficult if not impossible to fill. Mr. Chamberlain said that he was not going to indicate any policy on the part of the Government in regard to the future of the voluntary hospitals, but he hoped if he were granted time enough, before he gave up his present office, that he might be able to do something to put this matter on some satisfactory and permanent footing.

NEW YEAR HONORS FOR MEDICAL AND SCIENTIFIC MEN

Knighthoods have been conferred on Dr. John Campbell, senior surgeon to the Samaritan Hospital, Belfast; Dr. T. Morison Legge, medical inspector of factories; Mr. Holburt J. Waring, formerly vice-president of the Royal College of Surgeons of England and Vice-Chancellor of the University of London; and Professor Gowland Hopkins, professor of biochemistry in the University of Cambridge; Dr. Henry J. F. Simpson, obstetrical surgeon, West London Hospital, has been given the R. C. V. O.

ENCEPHALITIS LETHARGICA IN LONDON SCHOOLS

The provision of separate schools for children who have suffered from encephalitis lethargica is said to be matter for consideration by the London County Council. It is stated that children who have had the disease often undergo an entire change of character. Not only is there physical deterioration, but they lose control over their emotions.

LATIN AMERICA NEWS LETTER

(From our own correspondent)

Balboa Heights, C. Z., *January 10, 1925.*

EFFICACY OF YELLOW FEVER VACCINE

Dr. Hideyo Noguchi, of the Rockefeller Foundation, has recently made some very interesting statements regarding the efficacy of his comparatively new yellow fever vaccine, based upon observations made in Central and South America. His vaccine is made from the killed cultures of the Leptospira icteroides. During the recent epidemic of yellow fever in San Salvador, the Noguchi vaccine was used extensively and with good results. Dr. Noguchi has been experimenting since 1919 with a view to determine its efficacy during epidemics. He concludes that the purpose of the vaccine is to provide temporary personal protection only; that the immunity is not lasting nor so general or durable as that induced by smallpox vaccine or by spontaneous infection. Based on the experiments that susceptible animals become resistant to the icteroides infection he assumes that vaccinated persons are protected for a limited time (duration unknown). There are a certain number of protective infections in cases developing in those vaccinated prior to the formation of definite immunity. Dr. Noguchi states that it is extremely rare that a person contracts yellow fever after a lapse of ten days after the last injection. To produce complete immunity two injections are necessary. During an epidemic there is observed a sharp and sudden drop in case incidence among vaccinated persons within ten or fifteen days after vaccination of a group. He concludes that aside from the question of efficacy of the vaccine, nothing should be done at present regarding any modification or relaxation of existing quarantine regulations.

GERMAN SETTLERS INFECTED WITH MALARIA

During the past six months quite a large group of German immigrants have colonized at Capira, Panama, with the intent of clearing the jungles and establishing farms. To date over thirty per cent. of the settlers have been infected with malaria which has handicapped greatly the progress of the work. Capira is in the lowlands and is badly infested with the malaria carrying mosquito. The Panama Government is taking care of the sick and precautions are being taken to prevent the spread to the unaffected. It is practically impossible for a European to settle in this part of the tropics without contracting malaria at some time or another. The transfer of all the colonists from Capira to the Provence of Chiriqui is now being seriously considered by the Panama Government officials. This province is in the highlands, is better suited for the white man and is considered good agricultural country, and is entirely free from mosquitoes. A committee from the Panama Rotary Club is also looking after the interests of the settlers and have made recommendations to the Panama Government to carry out eradicative measures for malaria at Capira. These German immigrants sold all their effects in Germany and migrated for Panama for the purpose of starting an agricultural community. So far their project has been a failure.

NOTED SANITARIAN VISITS SOUTH AMERICA

Assistant Surgeon General John D. Long of the United States Public Health Service and Medical Director of the Pan American Sanitary Service, passed through the Canal recently on his way to Lima, Peru, and other places in South America. Dr. Long was accompanied by Mr. Charles La Gorce, vice-president of the National Geographical Society. Both of these gentlemen are delegates to the Pan American Scientific Congress at Lima. On arrival at the Canal these distinguished scientists were met by Dr. C. P. Knight, chief quarantine officer of the Canal, and escorted across the Isthmus, where they remained until the departure of their ship for South America. Dr. Long and Mr. La Gorce will make an extensive study of health conditions and administration in the South American countries before they return to the United States. Mr. La Gorce is also obtaining material for the Geographical Society.

PAN-AMERICAN SANITARY CONFERENCE

The Pan-American Sanitary Conference which met this year at Havana, Cuba, adopted a sanitary code of sixty-three articles and approved a draft of a model food and drug act. The delegates selected Lima, Peru, for the next conference and elected as their president Dr. Carlos Paz Soldan, professor of hygiene and preventive medicine of the University of Lima. Surgeon General Hugh S. Cumming was reelected director of the Pan-American Sanitary Bureau and Dr. John D. Long was chosen assistant director. Dr. M. G. Lebredo, of Cuba, was elected honorary director of the bureau. The new sanitary code was prepared in the main by Dr. Long, and some of its features include: a provision that the signatory governments agree to designate landing places for aircraft which shall have the same status as a quarantine station. Obligatory reporting at intervals of not less than two weeks is required for epidemic cerebrospinal meningitis, acute poliomyelitis, epidemic encephalitis, epidemic influenza, typhoid fever, paratyphoid fever and the maritime quarantinable diseases. The conference passed resolutions, specifying for the next conference the special study of plague and child welfare and intestinal parasites. Cuba was congratulated upon the formation of its Public Health Service and calling upon other nations which have not done so, to organize their public health service as a stable and definite part of the government, with the chief of the service as a cabinet minister.

FOOD POISONING AMONG JAPANESE SAILORS

During the recent visit of the Japanese warships to the Canal Zone, two hundred sailors of the *S. S. Yakumo* were taken suddenly ill after a hearty meal. Symptoms of food poisoning were present with violent vomiting and purging. The illness was promptly investigated by the medical officers of the ship and laboratory examinations made in order to determine the causative agent of the illness. Investigations revealed the fact that the sickness was caused by dried fish brought from Japan, this being a part of the sailor's ration. Although the symptoms were quite severe, there were no fatalities, and all were able to return to duty in a few days.

Book Reviews

TREATMENT OF DISEASES

Fundamental Principles in Treatment. By Harry Campbell, M.D., B.S., F.R.C.P. Lond. New York: William Wood & Company, 1924.

This is an excellent book, and senior medical students and all practitioners of medicine would be benefited by acquiring the broad view of the treatment of disease and diseased conditions as presented by the author. The medical student quite generally graduates with the idea that the treatment of disease is of minor importance, that the diagnosis and pathology are of supreme importance, while as a matter of fact the science of pathology and the art of diagnosis are means only to the end of therapeutics, and therapeutics may be diet, exercise, medication, or general or special surgery.

The author begins with a description of the requirements of the practitioner for success. He refers to quackeries and the innate tendency of many diseased conditions to be cured by Nature's processes. He emphasizes the study of the patient himself and his habits as modifying the treatment or care that he needs, and decries the running to fads in the treatment of disease by some physicians. While the author is a little too strong perhaps on the influence of heredity, we certainly do inherit our endocrine glands and their activities, which certainly modify disease and diseased conditions. The author is splendidly alert to the dangers of focal infection and especially of mouth infection. His discussion on the character of the blood plasma is well emphasized. Not enough investigation is made of the chemistry of the blood plasma. He gives a long sensible discussion of psychotherapy, and has chapters on fresh air, ventilation, clothing, exercise and rest. He interestingly discusses food and the evolution of diet.

This book will make the practitioner "stop, look and listen" before he treats his patients.

INSULIN

The Insulin Treatment of Diabetes Mellitus. By P. J. Cammidge, M.D. (Lond.), D.P.H. (Camb.). Second Edition. New York: William Wood & Co.; Edinburgh: E. & S. Livingstone, 1924. Pp. v-216.

A concise summary of the properties, mode of action, and sphere of usefulness of insulin, as known today, is presented. The author seems peculiarly fitted for this task, as the manufacture of insulin was commenced in his private laboratory and also because the patients treated by him with insulin were kept under most careful observation for periods of twenty years and more and their state of metabolism was accurately known as a result of exhaustive analyses of the blood, urine and feces. The author is, therefore, entitled to speak authoritatively. Study of the effects of insulin therapy have enabled him to provide a theoretical and practical basis for the classification of glycosurias. This, the second edition of this book, brings the entire subject matter up to date.

The discovery of insulin, the experimental investigations with it, and its method of action are reviewed. It is suggested that insulin is possibly an albumose, as it has many properties of the latter. Its clinical effects include the abolition of glycosuria, the disappearance of ketone bodies from the urine and blood, the reduction of blood sugar, the return to normal of the alkali reserve and the alveolar carbon dioxide, the increased utilization of carbohydrate by the body and well marked clinical improvement. It is a specific for diabetes. At the present time the vegetable kingdom cannot be expected to become a therapeutic source of insulin, as has been suggested.

Endocrine deficiency of the pancreas is no doubt the underlying pathology of diabetes mellitus. Systematic examination of the blood in all cases before insulin treatment is commenced is the safest guide as to whether insulin may be safely given or not, as insulin is not to be given indiscriminately. Intercurrent infectious diseases, acidosis, and gangrene can be successfully combated by the prompt administration of insulin.

The author's methods of insulin therapy are given in detail. The value of physiological rest for the organs of digestion and assimilation of food is emphasized. It is shown that the abnormal conversion of glycogen may be due to the following: 1, changes in the fixed acid to base equilibrium of the blood to the acid side; 2, hyperfunction of the ductless glands other than the pancreas, particularly the pituitary and thyroid; 3, nervous influences. Before insulin therapy is instituted the excessive permeability of the kidneys (renal glycosuria) must be differentiated from true diabetes mellitus.

The treatment also includes the eradication of septic foci, the control of hepatic and renal insufficiency, the assistance of elimination by the introduction of large volumes of fluid into the body, as well as gastric lavage, catharsis, cardiac stimulation, rest in bed and warmth. In general practice an initial period of instruction for the patient is essential.

The Folin and Wu method of estimating blood sugar and the Benedict test for the detection and estimation of urine in the sugar are recommended. The Addendum, including the up to date review of the action of insulin, and the nature of diabetes, the preparation and nature of insulin, the susceptibility to insulin and its administration, clinical notes, and the treatment of nondiabetic conditions, with insulin, is very practical and useful.

PNEUMONIA

The Pneumococcus and Pneumococcal Affections. By L. Cotoni, C. Truche and Mlle. A. Raphael. English Edition by D. S. Page, M.A., M.B.Cantab., D.P.H., Victoria Park, and Eva Morton, M.R.C.S. Eng., L.R.C.P. Lond. London: John Hale, Sons & Danielsson, Ltd., 1924. Pp. viii-218.

This monograph is divided into three parts: 1, the bacteriological study of the pneumococcus; 2, the habitat of the pneumococcus and the diseases of pneumococcal origin; 3, the treatment of such diseases. Emphasis is laid on the well established facts on which future research may be built, especially the studies carried out in M. Nicolle's laboratory. The results of these investigations are also correlated with those of other investigators.

The chapter on the pneumococcus includes studies on its morphology, its cultural characteristics, pathogenicity, evolution of virulence, immunology, agglutination, pneumococcus types and the preparation of antipneumococcus serum. The organisms classed as Streptococcus mucosus capsulatus are included among the pneumococci. Attention is called to the misconception, due to loose terminology, that the type IV pneumococci, which are not agglutinated by the sera of the types I, II, and III, are closely related to one another. The types of pneumococci are essentially agglutination types.

The study of the habitat of the pneumococcus in the intestines, outside the animal body and in the lower animals, tends to support the view that this organism is ubiquitous in the animal kingdom and that it is habitually present in certain mucous membranes in healthy man. The pneumococcus is found in the following body systems: the respiratory, circulatory, alimentary, genitourinary, nervous and special sense organs, ductless glands, locomotor system and the skin. In the colored races pneumococcus infections are more nearly akin to septicemia, or rather septicopyemia. Evidence is brought forth that the crisis in pneumonia should be included among the phenomena of hypersensitivity. The pneumococcus and the streptococcus can be differentiated by direct examination for the presence of the pneumococcus (bacteriological) and by the biological reactions of the blood. The resistance of patients varies in each individual, as does also the virulence of the organism. We can judge only by their combined effect, as expressed by the clinical picture.

The chapter on treatment is mainly a critical study of the value of serotherapy. The value of prophylactic vaccination and bacteriotherapy, as well as of chemotherapy, cannot as yet be estimated.

This work is a valuable résumé of existing knowledge of the pneumococcus. The bibliography is very comprehensive and includes references to French, English, American and German references.

VISUAL DIAGNOSIS

Diagnostik mit freiem Auge (Ektoskopie). Von Dr. Eduard Weisz. Mit einem Vorwort von Geh. Med.-Rat Prof. Dr. Friedrich Kraus. Mit 18 Abbildungen im Text. Berlin und Wien: Urban & Schwarzenberg, 1924. Pp. vi-136.

The ever increasing number of technical aids and laboratory methods has the inherent danger of the neglect of the powers of observation with the naked eye. It is the author's aim to develop the faculty of inspection. Through the observation of respiratory and phonation phenomena and the use of a few technicalities he has developed a special method of investigation, called ectoscopy. With it the physician is enabled to determine a series of noteworthy phenomena at the surface of the body which are of interest not only from a didactic viewpoint, but also have a practical and diagnostic significance.

The signs observable on the moving thorax include the respiratory phenomenon during quiet respiration and rapid respiration, the sniffing phenomenon and the speech or phonation phenomenon. The signs observable on the resting thorax are the sunken ribs and the forms, position and size of the splenic and hepatic islands. Their genesis and localization, both with and without röntgenography, are discussed as well as the technic. The speech phenomenon in the region of the stomach, the signs near the heart and the condition of the phrenocostal sinus are studied and their clinical values are determined. Pleuritis exudates are easily mapped out. This method of investigation is also applicable to neurological conditions.

THE CORTEX

Le Cerveau et la Pensée. Par Henri Piéron. Paris: Librairie Félix Alcan, 1923. Pp. iii, 327.

The author has called to his service the revelations of psychology and the physiological development of the nervous system from its simplest beginnings to its utmost complexities of cortical functioning. Only thus, in the manifestation of function, developing with organism, and dynamically preparing the complicated structure in the organism can the final interrelations of the complicated mechanism be approached in understanding. The contradictions existing between neuroanatomical findings and clinical facts, the failure of expectation thus to solve problems, have kept the cortical field in obscurity. The author's method illuminates where static modes of investigation fail. Piéron considers that, having arrived in development at the high cortical level, we have here an instrument of marvelous refinement for the pursuit of the problems. This is that of the most advanced evolution of language. To this, in the normal functioning and the disturbances of speech, he devotes several important chapters.

PATHOLOGY

Allgemeine und experimentelle Pathologie. Nach Vorlesungen für Studierende und Arzte. Von Dr. Hermann Pfeiffer. Mit 50 Abbildungen im Text und 8 teils mehrfarbigen Tafeln. Berlin und Wien: Urban & Schwarzenberg, 1924. Pp. xvi-594.

The author was impelled to write this book by the lack of an up to date book that is suitable for the needs of the medical student. It is entirely different from the usual type of book on pathological physiology. General pathology is utilized for its highly educational value to enable the student to understand the origin and nature of disease. The material is arranged in such a manner that the reader progresses from the more easily understood to the more difficult subjects. Not only actual knowledge but also the processes of thought and the necessary experimental methods; the how and why of experimental investigation, are emphasized. Only the most important and extensive German references to the literature are cited at the end of each chapter, so as not to distract from the main purpose of the book—teaching. It gives the medical student a broad outlook on the subject of disease from the viewpoints of etiology and pathology. There is nothing like it in the English literature.

After a general discussion on disease processes and the reaction to disease in the body, the various external causes of disease and the resulting diseases are discussed. In this chapter, five different types of results of infection are described under an entirely new classification, which stresses types of reaction. In the subject of inflammation are included the etiological factors, tissue injury, local and

general reactions in the body and the significance of the individual forms of inflammation. A separate chapter is devoted to the study of fever. The various types of immunity and their reactions are discussed. Blood diseases are studied from the point of view of the pathology of its cells and the circulation from that of the general and local disturbances in the body. The chapter on respiratory disturbances is illuminating. In the discussion of the metabolic disturbances, the food elements and their relationship to metabolic diseases and the manner of their affecting the different organs of the body are stressed. The subjects of endocrinology and endocrine disturbances are treated in a most comprehensive and interesting manner. The final chapter on experimental investigations of neoplasms takes up the various theories of causation as they have been promulgated and subjects them to criticism. The author favors the theory that neoplasms, both benign and malignant, are associated with metabolic changes. The purpose of the book is fulfilled.

MOTIVES FOR MURDER

Murder and Its Motives. By F. Tennyson Jesse. New York: Alfred A. Knopf, 1924.

The effort at classification follows a descriptive one and in no way attempts a deeper analysis of the underlying component factors. Unfortunately the book will have only a superficial value. The only way in which the problem can be attacked today so as to serve a purpose of value is to take into consideration the more profound analytical if somewhat more modern psychological concepts.

PHYSICIANS' OATH

The Doctor's Oath. An Essay in the History of Medicine. By W. H. S. Jones, M.A. Cambridge: The University Press, 1924. Pp. 62.

This work on the original oath is a splendid one. It contains the Christian oath which is published for the first time. Many manuscripts have been collected from various parts of the world and subjected to a critical survey. Historians of medicine should appreciate this excellent piece of work which has been presented in a most attractive fashion.

AUSTRALIA

The Boy in the Bush. By D. H. Lawrence and M. L. Skinner. New York: Thomas Seltzer, 1924.

Two things would make this new book of Lawrence's worthy, no matter under what heading: the reality of the boy pictured, and the strange essence he gives to that vast continent so little known to Americans. From the quivering, vaguely self-knowing lad new to the shores of Westralia, to the complete master of his soul that Jack Grant becomes in the end when he casts in his lot with the new country, the being has grown, developed, not so much under our eyes, as, unawarely, within us. How it is done is Lawrence's gift. One cannot spot it, say this makes for such an effect, that hits you there. He probably would not know either how it was done —but it *is* done and masterfully.

The boy is only one of millions who have grown through adolescence to manhood in "the bush." One has a dim feeling of Australia itself like a man in the prime of life, still able to remember whimsically the mistakes of giddy youth, but with the conviction of splendid service given and still to give.

Certain of Lawrence's mannerisms and theses are still being ridden hard. One wonders what M. L. Skinner's contribution was—for not a paragraph but has the tricks of iterative wording that sometimes jar, but nevertheless serve unconsciously to paint the mosaic Lawrence is after. Yet the "feel" of the new land is there, the knowledge that can only soak in after long association. There is perhaps a little more than the usual amount of sensuous imagery,—color—smell—halflights. Yet they are not unfamiliar to Lawrence's style—we find them richly manifest in his poems. Whatever the task of the collaborator it has made for an increase in depth in the book that brings it to the high level of Lawrence's works, sharply contrasting it with *Kangaroo*.

One of Lawrence's pets—the practicability of polygamy (for men only—Lawrence's women apparently do not stop to ponder about it) is aired with the customary frankness. His hero would like to put his theories into practice. Everyone feels he would be quite mad enough to try, so everyone conspires to "save him from himself." But what about the sociological end of it, the deep lying problem of many modern countries in the past twenty years where women have been steadily outnumbering the men? The woman's angle has not come to our attention as much as the growing undertone in Lawrence's books and those of others of his generation. And linked with the frankly tribal polygamous suggestions run others at the same free life level—the associations of young men, friendships, loves, so completely laid bare in *Kangaroo*.

The Boy, and The Bush. Two pictures that we consider well-nigh flawless!

Medicoliterary Notes.

One of Macmillan's recent publications is *The Pipe Book* by Alfred Dunhill, a history of pipe smoking from the earliest written description of the pipe in Ovieto's *History of the Indies* to the present day. Mr. Dunhill writes that the implement referred to by Ovieto was not the pipe as we know it today, but a two pronged, Y shaped tube through which tobacco or other smoke was inhaled by placing the two prongs in front of the nostrils.

* * *

The New York State Department of Labor has issued as *Special Bulletin No. 131* an analysis of one hundred accidents on power punch presses, with suggestions as to the installation of suitable guards on such machines.

* * *

Excavations have recently revealed in the plains of the Indus River in India remains of a civilization more than five thousands years old, a period twice as long as that of which it had hitherto been possible to speak with any certainty. A description of these excavations and the findings has been written for the *Pioneer* by Sir John Marshall, director general of archeology, according to an editorial in the *Manchester Guardian*.

* * *

An interesting and useful map has been issued by the United Hospital Fund of New York which gives information about hospital facilities of the city in great detail and completeness. Ambulance districts, municipal and other hospitals, and some of their outstanding characteristics, street numbers, etc., are given in a form available for quick use.

* * *

Twins are more frequently lefthanded than are the single born, according to investigations conducted at the Siemens

Works, manufacturers of electrical apparatus. Fifteen per cent. of the twins examined were lefthanded, while only seven per cent. of the others qualified as "lefties." Another interesting fact brought to light is that lefthandedness, contrary to general belief, is not hereditary. There seems to be a definite relation between lefthandedness and stuttering, it having been found that 22.5 per cent. of the lefthanded employes were stutterers, while only nine per cent. of the righthanded had this defect of speech.—*Herald-Tribune.*

* * *

Dr. Duncan L. Bulkley, of New York, has recently brought out a privately printed booklet about his life and work. Dr. Bulkley's practice has been for the most part in New York and has extended over a period of more than fifty years. He was one of the founders of the American Dermatological Association and of the American Association for the Study and Cure of Cancer.

* * *

The *Living Age* for January 10th quotes from *Le Temps* of Paris an interesting article by Jean Carrère on The Love Affairs of Stendhal. Stendhal's real name was Henri Beyle, he was French consul to Rome, and the author of a number of well known books of which the most famous perhaps is *L'Amour.* Carrère writes that his ideal in history and legend was Don Juan, yet never a man lived who was more the opposite of the knight of the masterful eyes, for Stendhal was painfully timid, especially with women, and had never a word to say when in their company.

* * *

As a result of the demonstration clinic that has been conducted at the University of Minnesota during the past year by the division on prevention of delinquency of the National Committee for Mental Hygiene, two permanent child guidance clinics have been established—one in Minneapolis and the other in St. Paul. A third clinic, a traveling state clinic from the University of Minnesota, has been developed to conduct clinical examinations and to do educational work directed toward the establishment of a state psychopathic hospital.—*Mental Hygiene Bulletin.*

* * *

Outward Bound, the play by Sutton Vane which had so successful a run in New York last season, has been produced this winter in Vienna, the German version having been made by Richard Beer-Hofmann. Press reports state that it was not so successful at the Josefstädter Theatre as was expected. Among criticisms were those that the plot dragged, that the happy ending was not good art, and that the play was too long and could have been more suitably given in one act.

* * *

Among publications of medical interest is *An Outline of Psychoanalysis,* edited by J. S. Van Teslaar and published by Boni & Liveright. The book is one of the Modern Library series and contains seventeen essays, the first by Freud, and others by Jung, Pfister, Putnam, Jelliffe, Stekel and others. Another book, of a more popular character, is *Safeguarding Children's Nerves,* by Dr. James J. Walsh and John A. Foote (Lippincott). *Educational Measurements and the Classroom Teacher,* by A. R. Gilliland and R. H. Jordan (Century), gives full information about the latest methods and equipment for psychological testing; *Smallpox and Vaccination* by Dr. Benjamin White, Harvard University Press, is a history of smallpox and its care and treatment especially for the layman; *Organic Adaptation to Environment,* edited by Malcolm R. Thorpe (Yale University Press), is a collection of articles by authorities on the subject; *The New Psychology and the Preacher* by Dr. H. Crichton-Miller (Seltzer) is as valuable as his similar works on applied psychology.

* * *

It was very little more than a hundred years ago—one hundred and five, to be exact—that Keats seriously pondered whether he should give up poetry and use the few pounds that remained to him in qualifying as a physician in Edinburgh. Taking fees, he said, was not so bad as "writing poems to be hung up and fly blown on the review shambles."—*Manchester Guardian.*

* * *

One of the most widely read books in Germany, according to book news from the Continent, is Alfred Kerr's *New York and London,* published in Berlin by Fischer. The author is a dramatic critic who has recently visited this country and the British Isles. He has much to say naturally of the American theatre and drama, especially the activities of the Theatre Guild; he describes New York as "gloriously impulsive . . . glowing with color . . . and having a genius and a future."

* * *

At the invitation of the Massachusetts Institute of Technology, a working conference in health education will be held on June 23d-28th at Cambridge.

* * *

Among American towns that have recently established the Beccari system of garbage disposal and found it most efficacious are Paterson, N. J., and Scarsdale, N. Y. The Beccari system, the invention of Beccari of Florence, Italy, was described in a recent issue of *The Journal.* It operates by natural fermentation carried on in cells and chambers and is simple in construction and inexpensive to build.

* * *

One of the most interesting novels of the year is *A Naked King* by Albert Ades, whose earlier collaborations with Albert Josipovici, *Les Inquiets* and *Le Livre de Goha le Simple,* are both well known, especially the latter which was published in English under the title *Goha the Fool.* According to the reviews, *A Naked King* is not so great a work as *Goha,* but is nevertheless a remarkable character study as well as an unusually interesting story. It is a portrait of a painter and a genius, with a background of Paris life.

* * *

According to a late report by Dr. Hoffman, the suicide record for eighty cities remained the same for 1923 as for 1922, namely, 15.2 in 100,000 population. The rate increased in thirty-four cities and decreased in forty-six. San Diego had the highest rate for both years. Cities with high rates were on the Pacific coast, while cities of the lake region showed low rates. Boston had a rate of 16.4, Manhattan and the Bronx 16.3, Philadelphia 14.4. and Washington 14.4.

* * *

A critical biography of unusual interest is Dr. Karl Obenhauer's *Friedrich Nietzsche* published at Jena by Diedrichs. A recent review has characterized the book as "done without hysterics, delusion, or social astigmatism."

* * *

The October issue of the *American Journal of Public Health* is a number of unusual interest. It contains, among other articles, The Outlook for International Vital Statistics, by Edgar Sydenstricker; Offensive Tastes in Public Water Supplies, by Dr. Charles F. Dalton; The Present Status of Health Education, Physical Education and School Medical Inspection, report from the Child Hygiene Section of the American Public Health Association; and an editorial giving statistical and other information showing that Public Health Work Pays.

* * *

The Triumph of Lord Palmerston, by B. Kingsley Martin, is not wholly, as the title implies, the study of an episode in the career of a famous statesman, but of the attitude of England before and during the Crimean war. Its chief value lies in its true and brilliant analysis of crowd psychology in war time, and it is a real and significant contribution to the literature of this subject. The book is one of the late publications of the Dial Press.

* * *

The enormous increase within recent years of divorces in central Europe, coupled with the disordered economic conditions, have left numerous divorced wives and their children totally without provision, which doubtless accounts for the publication of a new semi monthly magazine in Prague entitled *The Divorced Wife.*

* * *

An exhibit showing the ravages of the Japanese beetle has recently been installed in the American Museum of Natural History. Dr. Lutz, curator of the museum, is quoted as having said that this insect may cause one of the worst insect scourges that has ever attacked the United States. The beetle has already made its appearance in New York City.

* * *

That the conservation of human energy is the greatest of all economic problems is the main contention of a new book by Prof. T. N. Carver of Harvard, entitled the *Economy of Human Energy.* Macmillan is the publisher.

Abstracts from Current Literature

CARDIOVASCULAR DISORDERS

Congenital Stenosis of the Conus Arteriosus.—Hermann Müller, Jr. (*Schweizerische medizinische Wochenschrift,* July 31, 1924) states that the uncomplicated congenital stenosis of the conus arteriosus is a relatively benign congenital lesion unassociated with cyanosis and compatible with long life. In the simple cases, not complicated by other cardiac malformations, the diagnosis can be made in life. This lesion is not rare, but heretofore it has been known too little to be diagnosed more often. It is characterized by a powerful, heaving apical impulse with a hardly perceptible pulse, by a loud systolic murmur and marked fremitus over the left ventricle, the aorta and the carotids and by the presence of the second aortic accentuation; the left ventricle is usually enlarged; the ascending aorta shows marked pulsation under the fluoroscope and is sometimes dilated. The first cardiac sound is often split; the second aortic sound may be accentuated. The pulse is sometimes retarded, but more often not. The right chambers of the heart are rarely also dilated and hypertrophied. The presence of malformations outside of the heart and bodily underdevelopment are noted exceptionally. There is no special predisposition to pulmonary diseases, as there is other congenital valvular lesions. Anatomically, diaphragmlike, ringshaped folds and valvelike formations are the cause of the stenosis. These are situated 0.5 to 1.0 cm. below the intact aortic valve and usually surround an opening of about 1.0 cm. in diameter. The left ventricle is usually markedly hypertrophied and slightly dilated. The ascending aorta is sometimes dilated. In a few cases the right heart chambers are also hypertrophied and dilated.

Periarterial Sympathectomy.—Kenneth Black (*British Medical Journal,* August 2, 1924) states that arterial decortication has been performed for various surgical conditions, but its utility seems to be greatest and the results obtained most encouraging in cases of trophic ulcerations of the extremities. Especially favorable results have been reported in perforating ulcer of the foot. In ulcers of the legs or feet it gives good results provided the ulcers are not very old or surrounded by much scar tissue. It has been tried with no inconsiderable success in Raynaud's disease, in frostbite gangrene, ischemic paralysis of the forearm, painful stumps, trophic contractions of muscles, and in some chronic cases of pains in the hands and feet (erythromelalgia). In two of the author's cases of ulcerations of leprosy the results were remarkable. This result warrants further trial in leprous ulcerations and also in Dupuytren's contracture. Decortication of the common carotid artery has been done for glaucoma and for trophic ulcer of the cornea, but no final conclusion can as yet be given in these cases. The operation is contraindicated in diabetes, in renal, hepatic, or cardiac disease, and in arterial degeneration. No bad symptoms have been observed after this operation.

Rheumatic Lesions of the Left Auricle of the Heart.—W. G. MacCallum (*Bulletin of the Johns Hopkins Hospital,* October, 1924) has noted several times in cases of rheumatism a marked thickening of the wall of the left auricle above the base of the more posterior leaflet of the mitral valve. This roughened patch somewhat resembles the vegetations so commonly found there in cases of endocarditis produced by the streptococcus viridans, but is evidently more largely produced by a new growth of tissue, and to a less extent by the deposition of rough fibrin on the surface. Though the surface is sometimes corrugated, it does not seem to be roughened by any thrombus mass. In several cases the thickened patch was very dense and scarlike, as though representing the late or healing stage after the subsidence of an earlier process. Microscopically there are changes in the wall of the auricle and in the tissue about the auriculoventricular junction and the enclosed coronary vessels as well as in the roots of the valves which resemble those found in the myocardium of the left ventricle, but far more extensive. There is great edema and actual new formation of tissue lifting up and spreading apart the inner wall of the auricle inside the muscle. The lining layer of the auricle, very rich in laminated elastic fibrils bound together by intervening fibrillæ, is spread apart by fluid and a great infiltration of wandering cells of many sorts, mostly mononuclears, but many polynuclears, and even lymphatic channels filled with lymphocytes formed a peculiar and rather conspicuous feature. The most striking thing was the numerous large Aschoff bodies composed of the characteristic large cells with large, deeply staining vesicular nucleus and indefinitely outlined cell body.

Spontaneous Interstitial Myocarditis in Rabbits.—C. Philip Miller, Jr. (*Journal of Experimental Medicine,* October, 1924) presents a report on the hearts of thirty-four apparently healthy adult rabbits, twenty, or sixty per cent. of whom showed myocardial lesions. On microscopic examination they were found to be distributed as follows, in order of frequency: papillary muscles, septum, left ventricle wall, right ventricle wall, auricles. No lesion was ever found in the valves or at the bases of the valves. The lesions consisted of lymphocytes and endothelial leucocytes in varying proportions, to which were sometimes added polymorphonuclear eosinophiles, plasma cells, and fibroblasts in small numbers. No microorganisms or cell inclusion bodies were found in the lesions.

Observations on the Respiratory Gases in Ventricular Paroxysmal Tachycardia.—Francis R. Dieuaide (*Bulletin of the Johns Hopkins Hospital,* August, 1924) reports a case of paroxysmal tachycardia of ventricular origin in which neither digitalis nor quinidine (separately administered) prevented or terminated the paroxysms. Quinidine was apparently followed by an unusual bigeminal rhythm due to ventricular contractions which were followed by the auricles. During the paroxysms retrograde heart block sometimes appeared. There was a decrease in the oxygen saturation of the arterial blood. There was also a significant reduction in the vital capacity. During an attack of tachycardia the basal metabolism showed an increase of sixteen per cent. The respiratory gases and basal metabolic rate were normal during the normal cardiac mechanism.

Transient Hemiplegia, Aphasia and Blindness in a Case of Aortic Insufficiency.—Barré and Cahn (*Presse médicale,* August 2, 1924) report a case of pronounced aortic insufficiency, with apparent good health, in which rightsided hemiplegia and aphasia developed and vision in the right eye was completely lost. After a few days the paralysis of the arm receded and disappeared. Motility of the lower extremity returned abruptly. Vision in the affected eye was restored in a few days, the pupil being, however, found still dilated and slightly less responsive to light. Such disorders are allied to those regarded as nervous disturbances due to circulatory spasm, and aortic insufficiency greatly favors the development of spasmodic circulatory manifestations.

Coronary Arterial Occlusion.—Herbert C. Gordinier (*American Journal of the Medical Sciences,* August, 1924) maintains that this presents a perfectly definite symptom complex, of which the following are the salient features: 1. Sudden severe anginoid pain, substernal or upper abdominal. 2. A pinched ashen gray or very pale facies, often associated with the sensation of impending dissolution. 3. An acute emphysematous distention of the lungs, with dyspnea or extreme orthopnea and moist crackling râles at the bases of the lung, together with the evidences of the acute onset of cardiac decompensation. 4. An easily compressed rapid thready pulse, which may present almost any form of arrhythmia. 5. A sudden drop in the systolic pressure following the severe pain and early myocardial exhaustion. 6. A cardiac impulse, if palpable, that is a diffuse feeble tap, distant heart sounds and often a tic-tac or gallop rhythm. 7. A localized pericardial friction rub, which is evanescent, appearing as early as a few hours or a day or two after the sudden onset of the agonizing pain. It may be missed if the infarct involves the posterior aspect of the heart. 8. A fever of short duration and of a mild type associated with a polymorphonuclear leucocytosis. This does not occur in simple angina pectoris. 9. Inversion or isoelectric position of the T wave, with arborization block. 10. Associated with the above described symptoms, the presence of a large tender liver, together with the symptoms and physical signs of pulmonary infarction, is suggestive of

thrombosis of the right coronary artery or its branches, while the sudden onset of pulmonary edema or recurring attacks, together with the development of sudden arterial plugging of the vessels of the brain, viscera or extremities, with the characteristic electrocardiogram, is highly suggestive of thrombosis of a branch of the left coronary artery.

The Pathogenesis of Dissecting Aneurysms.—R. G. Whitman and Herman B. Stein (*Journal of Medical Research,* September, 1924, describe a case of dissecting mesaortitis in which there was an extensive splitting of the aorta and its branches at the arch with the formation of a large aneurysmal sac, containing only lymph. There was no break in the continuity of the intima. This case, the authors believe, establishes the socalled dissecting mesarteritis of Babes and Mironescu on a firm foundation as a separate disease entity, and as the most frequent cause, at least, of dissecting aneurysms. It also brings strong support to the theory of Krukenburg that a dissecting aneurysm may arise by hemorrhage from the vasa vasorum, instead of from the lumen proper.

Lesions of the Aorta Associated with Acute Rheumatic Fever, and with Chronic Cardiac Disease of Rheumatic Origin.—Alwin M. Pappenheimer and William C. Von Glahn (*Journal of Medical Research,* September, 1924) studied the aortas from seventy-six rheumatic patients, and those of seventy-seven controls dying from various conditions. A series of aortas from syphilitic patients was also included for comparison with the lesions in the rheumatic group. A detailed histological description is given. The rheumatic group showed certain lesions in a much higher percentage than in the controls, and these lesions seem to be characteristic of rheumatic infection. The most distinctive lesions were dense scars in the vicinity of the nutrient vessels, often acellular, and Aschoff cells or nodules in the adventitia.

Some Cardiac Effects of Atropine.—Robert Dawson Rudolf and F. M. R. Bulmer (*American Journal of the Medical Sciences,* November, 1924) say that atropine has two distinct effects upon the heart rate when this is regular. In small doses it merely slows it, probably by stimulation of the vagal centres. In large doses, of course, it hastens it by paralyzing the vagal endings in the heart. It also then tends to remove any existing heart block. If the dose is neither large nor small there will be no change in the heart rate, the two effects of stimulation of the vagal centres and partial paralysis of the nerve endings neutralizing each other. As already mentioned, individuals vary very much in their reaction to atropine. In most adults one one hundredth grain will merely slow the heart, in some no effect will occur while in a few a slight hastening sets in. In the last two groups it is usually only necessary to lessen the dose to get the slowing effect.

Physiological Processes of Acclimatization to High Altitudes.—A Loewy (*Schweizersiche medizinische Wochenschrift,* May 29, 1924) states that the proper acclimatization to high altitudes depends upon changes that are directed against the reduction of the pressure of the oxygen and have for their purpose the increased access of oxygen to the tissues. The increase in the frequency of the pulse and of respiration must be considered as the effect of the unaccustomed climatic stimulation. The saturation of the blood with oxygen at a relatively slight altitude (1550 metres) is almost as extensive as in the valley and does not explain the initial dyspnea with muscular work. At a level of more than 3000 metres and with a corresponding dilution of air in the penumatic chamber the alkalinity of the blood is reduced more markedly with muscular work and abnormal acids appear in greater abundance. An increase in the total volume of the blood, particularly of the hemoglobin and of the number of the cells, anisocytosis and polychromasia as an expression of an increased delivery of erythrocytes into the blood and an increased gaseous metabolism have been recently demonstrated, as well as an increased combination of the oxygen with blood pigment. Other signs of acclimatization are the increase of the respiratory volume, of the tension of the oxygen in the alveoli, of the circumference of the thorax and of the vital capacity. Finally, the pigment formation in the skin must also be looked upon as a sign of acclimatization, which pigmentation protects the more deeply lying layers against the inflammatory effects of the ultraviolet rays.

Partial Occlusion of the Aorta with Silk Sutures, and Complete Occlusion with Fascial Plugs.—Mont R. Reid (*Journal of Experimental Medicine,* September, 1924) produced by means of Halsted mattress sutures of silk partial occlusion of the thoracic aorta of dogs in two cases, and of the abdominal aorta just above the inferior mesenteric artery in six cases, in all of which the partial occlusion persisted. Complete occlusion (without infection or hemorrhage) of the aorta of dogs by means of fascial plugs was produced by the method described. The wall surrounding an occluding fascial plug does not die, though it atrophies for a considerable distance below the occlusion, whereas the wall above maintains its normal thickness and size. Ligatures and encircling metallic bands used for ligating or plicating large arteries cause death of the arterial wall. The use of catgut for the ligation of large vessels is dangerous, as it may give way before the necrosed wall becomes completely substituted by fibrous tissue.

A Cardiovalvulotome.—Claude S. Beck and Elliott C. Cutler (*Journal of Experimental Medicine,* September, 1924) have devised a surgical method and instrument applicable to the treatment of mitral stenosis. A valvulotome has been made which is a powerful cutting device which will actually excise a piece from the stenosed ring and remove the piece from the blood stream. The efficacy of the instrument has been tested by its use on the stenotic valves of diseased hearts removed at autopsy. Its feasibility has been shown by operation on animals and in a single human case in which a segment of the stenosed mitral valve was excised and removed from the heart.

A Comparative Study in Digifolin Administration.—Norman E. Clarke (*American Journal of the Medical Sciences,* August, 1924) made a comparison of different preparations of digitalis given by different methods. In comparing the rapidity of action as measured by the slowing of the heart rate it was noted that an average slowing of the rate is obtained between three and four hours by intravenous, say about four hours by intramuscular, and at six hours by oral administration. The amount of digifolin required to show the earliest and full therapeutic effects is about equal for intravenous and intramuscular injection. By oral administration is required about half again as much of the drug. The average time required for digifolin to show the earliest and maximum effects with the three methods of administration has been obtained. The comparison of these time intervals closely approximates the comparison of the digifolin requirements. Intensive therapy may yield an unfavorable result. The use of digitalis by other than the oral method is not advocated. An important factor in treatment is the cost of different preparations of digitalis.

Operation Shock.—J. Fraser (*British Journal of Surgery, January,* 1924), reaches the following conclusions regarding the nature of surgical shock. The essential underlying factor in the production of the shocked condition is a prolonged and progressive fall in blood pressure. The causes which inaugurate the original fall are various; some are nervous, some are clinical, in many instances there is a combination of causes; hemorrhage, sepsis, and the absorption of toxic products from injured tissues are collateral and sustaining factors of great influence. With the establishment of a persistently low blood pressure something of the nature of a vicious circle comes into play, the prolonged hypotension leads to imperfect oxygenation of the body tissues, and to a capillary stasis; the capillary stasis reduces the amount of blood in active circulation, and the imperfect oxygenation of the tissues results in the formation of various toxic products from imperfect tissue metabolism. These influences collectively further reduce the blood pressure, the vicious circle is maintained, and the tendency is for it to continue to a fatal issue unless some link in the chain is broken and the hypotension error is overcome.

As to its physical manifestations, the influences of general anesthesia and surgical operation upon shock, and their respective remedies, he offers the following: If, during the progress of a surgical operation of any magnitude, certain investigations are made, it will be found that three changes have appeared: 1. There is a lowering of the systolic blood pressure. 2. Examination with the hematocrit shows a gradually increasing concentration of the blood. 3. There is a reduction of the alkali content of the plasma. In fact, during the progress of the operation there has been

the inauguration of the three processes which have such an important influence upon the institution of the shocked condition. In the large proportion of cases these various changes are so slight that little clinical evidence of their presence is apparent, but none the less they are the basis of shock, and under unfavorable conditions they may assume dangerous proportions. If the development of these features is to be kept within the limits of safety (their complete avoidance is impossible), certain precautionary measures are necessary, and these may be summarized as follows:

1. Operation in a case which shows persistent low blood pressure should be delayed, if possible, until means have been taken to raise the blood pressure. 2. The operative procedure should be as short as is consistent with thoroughness. 3. The operation should be carried out with the least possible interference and trauma. Every effort should be made to avoid unnecessary loss of blood. 4. Chilling of the patient before, during, or after the operation must be avoided. 5. If it is possible to exercise a choice of anesthetic, nitrous oxide and oxygen should be chosen. 6. If simple restorative measures have failed to raise the blood pressure before operation, it ought to be raised artificially by the intravenous infusion of human blood or of one pint of six per cent gum acacia solution in normal saline. 7. If examination of the blood shows that a condition of acidosis is present before operation, a reserve of alkali should be built up by the intravenous infusion of one pint of four per cent solution of sodium bicarbonate.

Orthopercussion with an Improved Threshold Percussion.—I Révai (*Wiener Archiv für innere Medizin*, April 1, 1924), advises the following technic: The terminal phalanx of the finger is placed over the area of cardiac dullness and the rest of the finger is kept at rest at an angle of forty-five degrees to the chest. Percussion on the finger continued proximally reveals absolute dulness near the first interphalangeal joint. When the finger plessimeter reaches the cardiac border the sound becomes suddenly clear. The author believes that this method of percussion may also be applied to the liver, kidneys and, especially, to the lungs.

Action of Quinidine on the Amphibian Heart.—J. A. Waddell and Morris Cohen (*Journal of Laboratory and Clinical Medicine*, September, 1924) employed turtles and frogs for this work. From this study it is concluded that quinidine produces its effect through action on the musculature of the heart, including that of the conducting system With moderate doses, there is no evidence of permanent tissue damage, all effects being abolished by withdrawal. Quinidine seems to be a physiological depressant, analagous to ether on the brain and cocaine on nerves.

Action of Potassium Iodide on the Circulation.—The work of D. Bloom (*Schweizerische medizinische Wochenschrift*, May 15, 1924) shows that more than half of the twenty-three patients examined exhibited a lowering of the blood pressure (ten to forty mm. of mercury) and also an increase of fifty per cent. in the pulse volume and an increase of seventy-five per cent. in the pulse frequency (three to thirty-three beats) and with one exception never a fall several days after the administration of even one gm. of potassium iodide by mouth. Consequently potassium iodide is a circulatory remedy; it makes the work of the heart easier through dilatation of the bloodvessels, it increases the number of pulse beats, and it increases the pulse volume.

The Myocardium in Noninfectious Myocardial Failure.—B. J. Clawson (*American Journal of the Medical Sciences*, November, 1924) has studied the anatomical changes in the myocardium in myocardial failure resulting from hyperpiesia, chronic glomerulonephritis, right ventricular hypertrophy, defective valves, luetic aortitis and adherent pericardium, and found no anatomical changes except coronary sclerosis and myocardial fibrosis. Coronary sclerosis of serious degree was present in 22.5 per cent. Myocardial fibrosis was found in a marked or moderate degree in 20.5 per cent. and in a slight degree in thirty per cent. There is usually a close correspondence between the situation and extent of myocardial fibrosis and the distribution and degree of the coronary sclerosis. Myocardial fibrosis is usually due to coronary disease, but occasionally rheumatic infections may give rise to a slight degree of fibrosis. Myocardial strain (hypertensive or nonhypertensive) is not a cause of myocardial fibrosis. Luetic myocarditis is rare. Myocardial failure is rarely due to anatomical changes in the myocardium. It may be explained as an exhaustion of the cardiac muscle. True chronic inflammation of the myocardium is very rare. What is commonly called chronic myocarditis is usually myocardial fatigue resulting from the various conditions mentioned above. Approximately half of the cases of myocardial failure show no anatomical changes in the heart muscle. The anatomical changes in the heart muscle are seldom sufficient in themselves to cause death.

A Preliminary Study of the Blood Pressure Following Reduction of Renal Substance.—James R. Cash (*Bulletin of the Johns Hopkins Hospital*, June, 1924) began these studies with the attempt to produce a renal insufficiency by excision of kidney tissue, and by ligation of renal vessels, in previously normal dogs upon which studies of blood pressure, blood chemistry, and blood volume had been made after operation, the studies were continued for two to four months. The total kidney substance was reduced at least fifty per cent. and a portion of the kidney which had been deprived of its circulation was allowed to remain *in situ*. A moderate elevation of both systolic and diastolic blood pressure occurred. No associated renal insufficiency, as manifested by chemical changes in the blood, was noted but where large amounts of kidney tissue were removed or rendered incapable of function by ligation of the renal vessels, the total output of phenolphthalein was decreased. There were no significant changes in the blood volume.

Elevation in Blood Pressure Produced by Guanidine Compounds.—Ralph H. Major and Walter Stephenson (*Bulletin of the Johns Hopkins Hospital*, June, 1924) found that guanidine, methyl guanidine and dimethyl guanidine salts produced a marked and prolonged rise in blood pressure, accompanied by a slowing of the heart and a decrease in the respiratory rate. The rise thus produced may be promptly abolished by the use of calcium chloride, either alone or combined with potassium chloride. These experiments prove that substances normally excreted by the urine have a marked and prolonged pressor effect.

Capillary Microscopy at the Nail Groove.—Ferdinand Schreiner (*Zentralblatt für Gynäkologie*, March 15, 1924) finds that the stases observed in the capillary system of the nail groove do not depend upon angiospastic condition of the entire organism in eclampsia and its premonitory stages as otherwise all the capillaries in the field would have to show similar circulatory disturbances and stases at the same time. These angiospasms have been shown to be the result of a stimulation of the vasomotor centre, because stases and increase of blood pressure are not associated.

Danger of Pregnancy in Heart Disease.—D. Grant Campbell (*Medical Clinics of North America*, May, 1924) draws the following conclusions:

1. Certain heart conditions are very adversely affected by pregnancy, and it constitutes for them a very real complication. Included in this group are auricular fibrillation, myocarditis, and mitral stenosis.
2. Marriage and pregnancy are not justifiable in cases of auricular fibrillation or myocarditis.
3. Should any woman after marriage present either of these conditions and subsequently become pregnant, she should be aborted and sterilized.
4. Cases of mitral stenosis with no evidence of myocarditis or of previous heart failure are capable of bearing one or two children with safety if carefully watched, but each pregnancy damages the mother's heart very considerably.
5. With close attention to the signs and symptoms of heart failure, as evidenced by breathlessness, palpitation, precordial pain, and râles at the bases of the lungs, one can forestall a breakdown in cases of mitral stenosis by interference, either by induction or by section, according as the special case may indicate.
6. Unless specially indicated, abdominal Cæsarean section is not as satisfactory a method in cases already showing some heart failure as induction of labor or vaginal section.
7. Certain other heart conditions are not much affected by pregnancy, and there is no need to advise against marriage on account of the lesion itself. This group includes mitral regurgitation, aortic regurgitation, aortic stenosis, and the congenital lesions.
8. Finally, it is evident that it is the heart muscle that is the factor of importance, and that all other factors are of consequence only in so far as they may involve it.

INFECTIOUS DISEASES

"Spasmodic" Diphtheria.—C. W. Ronaldson (*British Journal of Children's Diseases,* July-September, 1924) states that diphtheria may be complicated by spasmodic nervous symptoms. They are most likely to be met with in patients who exhibit a nervous predisposition. Such symptoms are rare, and it is doubtful if they can occur in patients who have not suffered from a diphtheritic angina. Further proof is necessary before we can admit a diphtheritic origin for symptoms met with in subjects who show no clinical signs of diphtheria.

Intravenous Injection of Antitoxin in Diphtheria.—Donald MacIntyre and D. W. McKay (*Lancet,* June 21, 1924) are convinced that the intravenous injection of antitoxin is of great value in severe cases of diphtheria. The toxic symptoms subside much more rapidly than after an intramuscular or subcutaneous injection. The onset of paralysis also appears to be diminished. The authors were impressed by the number of cases in their series in which there was no paralysis. On the other hand, they do not advocate giving antitoxin intravenously in mild and moderate cases, where intramuscular injections have proved sufficient. As the reaction which usually follows an intravenous injection is sometimes severe it seems unnecessary in moderate cases to expose patients to the discomfort of such a reaction. For this reason they have only used the intravenous route in severe cases where there has been a definite risk of the disease proving fatal. The injection itself is simple and comparatively painless and it can be performed in young children.

Scarlet Fever Otitis.—E. H. R. Harries and F. Brayshaw Gillespy (*Lancet,* April 26, 1924) describe the clinical manifestations of scarlet fever otitis as follows: 1. The onset in about half of the cases is painless; if occurring in the acute stage of the disease, pain is more likely to be complained of than when the complication arises during the convalescence. 2. A small rise of temperature should always suggest an examination of the ears. The rise often precedes the otitis by a day or more. Timely paracentesis in these cases should be of value. 3. Symptomless discharge may be the first indication. In early life the membrane ruptures extremely easily, probably owing to its finer texture at this age. This mode of onset is more common in children under five. 4. Mastoid complications are rare under five years of age. Scarlet fever does not, as a rule, cause a rapid destruction of the membrane in the early stages of the disease if properly treated. Large perforations very often completely heal before the patient is discharged from the hospital. This fact is important from the point of preventive medicine, for an ear with perforation is more prone to future attacks of suppuration than if the membrane were intact. Early and energetic treatment is the most economical means of dealing with this large class of patients.

Indications for the Radical Mastoid Operation in Otitis Media Purulenta Chronica.—H. H. Burnham (*Canadian Medical Association Journal,* May, 1924) says that there are two clinical indications on which the surgeon should base his decision whether to wait until the more acute symptoms have subsided, or to operate at once for the safety of the patient. These are, 1, any danger signs, and 2, the type of infection. Danger signs include indications of meningeal irritation, headache, photophobia, tonic spasm such as affects the muscles at the nape of the neck, vomiting and many other of the well known symptoms of meningeal irritation. Important as a warning would be increasing signs of labyrinthine involvement, such as impairment of hearing, vertigo, vomiting, nystagmus, and signs of involvement of the lateral sinus as indicated by the two cardinal symptoms of fluctuating temperature, chills and positive blood culture; the latter in particular in the absence of any other possible source of a septicemia such as pneumonia or erysipelas. Lastly, one must look for symptoms leading to a suspicion of extradural or brain abscess In the absence of rapid disappearance of these danger signs, it may be considered safe to allow the more acute inflammatory action to subside. The advantage gained is the limiting of the progress of invasion by an efficient wall of defence. If now the operation is carried out every use should be made of the natural barrier formed by the inflammatory process. It should be left undisturbed unless hiding a deep seated focus of infection.

The type of infection with which one is dealing is of far more practical value, as a rule, than is generally believed. If the streptococcus be found in the discharge, the chances of cure without operation are much lessened and the danger of waiting much increased. If Streptococcus capsulatus is found, it is considered a positive indication for operation. This infection gives rise to such an insidious process that clinical signs are ill marked and grave damage may occur without any danger signs having arisen. Much of this information can be obtained by examination of the discharge before operation. If, for example, the Streptococcus hemolyticus be found on direct smear or after cultivation it is quite reasonable to surmise that this coccus is responsible for the acute process. And it is undoubtedly of additional value in forming a judgment as to the prognosis in the case.

Acute Pyogenic Parotitis in Otherwise Healthy Individuals.—Roy G. Spurling and Fred W. Stewart (*Boston Medical and Surgical Journal,* May 15, 1924) say that pyogenic parotitis in otherwise healthy persons does occur, and perhaps more frequently than is generally recognized. The condition must be distinguished from mumps, lymphadenitis, neoplasm, and cellulitis of the face and neck. The diagnosis may be made with certainty by careful observation of Stenson's duct and by catheterizing the duct in doubtful cases. The catheter specimen obtained from the parotid duct in septic conditions of the gland will yield an abundance of polymorphonuclear leucocytes and a pure culture of organisms. Expectant treatment should be carried out until definite fluctuation occurs, then surgical drainage should be established. The cases of pyogenic parotitis in otherwise healthy individuals tend to run a mild course and a spontaneous recovery is often made. On the other hand, when the condition occurs in a severely debilitated patient, the condition is much more serious and the prognosis should be guarded.

Treatment of Scarlet Fever with Dochez's Antiscarlatinal Serum.—Francis G. Blake (*Boston Medical and Surgical Journal,* July 10, 1924), says that a clinical and laboratory study of Dochez's antiscarlatinal serum has shown that it is a valuable therapeutic agent in the treatment of scarlet fever. The observations which warrant this conclusion are as follows:

1. Intracutaneous injection of the serum in patients with scarlet fever produces a local blanching of the rash at the site of the injection.
2. Intramuscular injection of the serum in therapeutic doses early in the disease is followed by rapid clinical cure, as evidenced by critical fall of temperature and pulse to normal, rapid fading of the exanthem, and prompt return to a state of well being.
3. The specific toxic substance present in the blood of patients with scarlet fever is neutralized in vitro by Dochez's serum. It promptly disappears from the blood following serum treatment.
4. The blood serum of scarlet fever patients acquires the capacity to blanch the rash in scarlet fever within a few hours after serum treatment.

Prophylaxis of Measles with Defibrinated Adults' Blood.—The results obtained by Helmut Gerlach (*Monatsschrift für Kinderheilkunde,* June, 1924), with the injection of adults' defibrinated blood for the prevention of measles were disappointing unless at least thirty c.c. of such blood was used for infants three to twenty months of age. At least forty c.c. had to be given to the older children. In only one patient of the fifteen treated did measles develop after the use of the smaller dose and in none of the three treated with the larger dose.

An Early Diagnostic Sign in Measles.—I. H. Goldberger (*Archives of Pediatrics,* June, 1924) noticed with unusual regularity, that children seen both in the preeruptive and in the eruptive stages of measles presented spots of a definite character on the swollen caruncle at the internal canthus of the eye. These spots are similar in color and in appearance, yet smaller in size, than the Koplik spots. During the eruptive stage of the disease, the spots have a tendency to coalesce giving the appearance of one large spot, but in the preeruptive period the spots appear isolated, pinpoint in size, from two to four in number, and bluish white in color. Both caruncles are usually involved. The eye spots can be seen from twenty-four to forty-eight hours before the appearance of Koplik spots, and in many

instances they have been recognized forty-eight hours prior to the onset of even the catarrhal symptoms, and if this sign is sought and found many children may be spared an unnecessary exposure. This eye sign has not been observed in scarlet fever or in other exanthemata.

Treatment of Pertussis with Intramuscular Injection of Ether.—Cleon C. Mason (*Archives of Pediatrics,* June, 1924) treated twenty-six cases of pertussis by the deep intramuscular injection of ether with very good results. The ether injections were made with a long, fine platinum needle, deep into the buttocks. Commercial anesthesia ether was used. The doses used were: First day, 0.5 c.c., two injections; second day, 1.0 c.c., two injections; third day, 1.5 c.c., two injections; fifth day, 2.0 c.c., one injection; each day thereafter, the same amount as on the fifth day. The injections did not seem especially painful.

The results were as follows: sixty per cent. of the patients stopped coughing and were apparently cured; twenty-four per cent. were definitely benefited; sixteen per cent. failed to respond or became definitely worse. Recently four additional cases were treated by the high rectal injection of 6.0 c.c of a forty per cent. ether solution in olive oil. These injections were repeated every six hours. Two of these patients stopped coughing quite promptly, and two failed to respond. This treatment can be carried out at the home.

Treatment of Chickenpox.—F. H. Thomson (*Clinical Journal,* August 13, 1924) advises the following: Most cases of chickenpox require little treatment, but it is necessary to take care that the lesions do not become infected. The patient should be kept in bed, and the lesions dusted with a powder of equal parts of boric acid, starch and zinc oxide. If the eruption is copious the patient should be bathed night and morning in a boric acid bath (one ounce of boric acid to one gallon of water). Indeed, the powdering and the bath relieve the itching. If pustules form on the face they should be incised, evacuated and cleansed with boric acid solution in order to avoid pitting. When crusts form, zinc ointment should be applied.

Bacteriophage in the Treatment of Typhoid Fever.—The bacteriophage employed by J. Smith (*British Medical Journal,* July 12, 1924) in the treatment of seven cases of typhoid fever was isolated from the feces of a normal individual who never had had an intestinal infection. It was obtained by the technic devised by d'Herelle. A bacteriophage showing some power to cause lysis of the bacillus typhosus having been obtained, its virulence was enhanced by filtering the broth culture through a bacterial filter and adding five drops of the filtrate to another broth tube along with a suspension of bacillus typhosus. The second broth culture was then incubated and afterwards filtered. By repeating this process fifteen times a bacteriophage of such virulence was obtained, that it produced lysis in a broth culture of bacillus typhosus in three to four hours. In five cases an immediate lysis occurred after the administration of the bacteriophage. In the two remaining cases, in which the blood culture showed the presence of bacillus typhosus, the bacteriophage had apparently no effect in modifying the course of the disease. The strains of bacillus typhosus obtained from the blood, the urine and the feces of the various patients were equally susceptible to the bacteriophage in vitro.

Pulmonary Amebiasis.—Philip Manson-Bahr (*Lancet* September 22, 1923) concludes as follows: 1. Pulmonary amebiasis may develop independently of hepatic abscess. 2. The pulmonary condition may simulate those of a bronchopneumonia or miliary tuberculosis. 3. The diagnosis is based upon the previous evidence of amebiasis, the leucocytosis, and the remarkable and lasting response to emetin and ipecacuanha. 4. Rupture of a hepatic abscess into the lung may take place without previous warning or the coexistence of hepatic symptoms. 5. The resulting pulmonary infection may closely resemble idiopathic disease of the lung, such as tuberculosis or bronchiectasis, both in local signs and general effects. 6. The therapeutic action of emetin and ipecacuanha is as striking in this as in the first condition described, and, as generally recognized, is more rapid and lasting than in amebic infections of the bowel. 7. Secondary infection of the respiratory tract with yeast fungi (monilia) may occur (socalled bronchomoniliasis). This appears to be of little diagnostic and possibly of no etiological importance.

Bed Isolation; Special Reference to Measles and Chickenpox.—E. H. R. Harries (*British Medical Journal,* March 6, 1924) concludes that bed isolation cannot replace small separate wards for the nursing of measles and chickenpox in their earliest phases; in their later and less infective phases the patients may be safely nursed under conditions of bed isolation. For short distances it is impossible to exclude the theory of aerial spread—possibly by bubbles in the case of measles. For distances of many feet human borne infection is much more probable. The later phases of measles and chickenpox can be successfully nursed with a wall space of nine feet for each bed. In the early stage a wall space of not less than twelve feet for each bed should be available. Protection by previous attack plays a part which always is important but which varies with different diseases and with the age distribution of the ward population.

Quartz Light and Vaccine Therapy in Pertussis.—King Grier Woodward (*Archives of Pediatrics,* August, 1924) employed the same technic in each of four cases of pertussis. The body was exposed to the quartz rays starting at twenty-six inches from the body with a three minute exposure. Each succeeding time the distance from the lamp to the body was shortened, and time of exposure lengthened, so that the skin showed a decided reddening for twenty-four to thirty-six hours after exposure. The vaccine used was stock pertussis glycerol vaccine, starting with 1,000 million Bacillus pertussis followed by two, four, six, eight thousand million. The time interval between the first three doses was three days, and five days between the third and fourth, and fourth and fifth doses. The earlier in the disease the case was treated the more rapid were the results. After each initial treatment there was decided improvement in the vomiting and the severity of the paroxysms. The subsequent treatments showed gradual improvement in all of the symptoms, which was especially noted within the first twenty-four hours after the exposure to the quartz light and administration of the vaccine. All signs of coughing ceased after the last treatment, which is very important in the author's opinion, as in the ordinary case of pertussis the patient has a slight cough which may persist for weeks or even months after the acute stages of the disease have subsided.

PEDIATRICS

Attempt to Vaccinate Children Against Tuberculosis.—Nathan Raw (*British Medical Journal,* July 19, 1924), treated 412 children, varying in age from 1.5 to 14 years, one of whose parents was suffering from pulmonary tuberculosis, with two prophylactic doses of a vaccine prepared from dead cultures of attenuated bovine bacilli. The injections were given at an interval of two weeks. No reactions were observed and in no case has there been any untoward symptom. However, a period of at least ten years must pe awaited before a final judgment can be given of its efficacy in all cases. The author is convinced that infection takes place most commonly in early life, and if we can with complete safety give some active immunity to those children who are directly exposed to infection at home, we will have taken a long step in the direction of prevention, which, after all, is the key to the problem.

Anesthesia for Short Operations on Children.—O. Stuart Thompson (*Lancet,* July 12, 1924), observed no bad effects from the administration of ethyl chloride in a series of ten thousand cases. He gives ethyl chloride on an open mask, the amount used being about three c.c. for a child five years old. It is sprayed on the mask, which is immediately applied over the face and is followed by open ether later on. The child is instructed to blow it away, and four "blows" with the inspirations that accompany them are usually sufficient to produce loss of consciousness. The child seldom struggles.

Oxidized Codliver Oil in the Therapy of Rickets.—Four cases of active rickets in infants, aged from five to twelve months, were treated by Richard Wagner and Hans Wimberger (*Lancet,* July 12, 1924), with oxidized codliver oil (heated for twenty-four hours at 120° C. with air bubbled through). The daily dose was ten grams and the cases, carefully controlled with regular x ray examination, showed satisfactory healing of the bone lesions at a rate rather slower than with the same dose of a potent, crude, untreated codliver oil. The growth promoting potency of the

two samples of oil, tested by growth experiments on rats, was found to be in the ratio of about 1 to 20. Assuming that a daily dose of ten grams of untreated codliver oil, when used in the therapy of rickets, does not provide any great excess of antirachitic principle, these observations lend support to the view that codliver oil contains two active organic factors: 1, antirachitic or calcium depositing, and 2, growth promoting (vitamine A), and that the latter is the more sensitive to oxidation at a high temperature.

Urticaria in Early Childhood.—Péhu (*Médecine*, August, 1924), notes that this disorder is much commoner in private practice than in the hospitals; gastroenteritis, especially with a tendency to athrepsia, is not attended with skin disturbances He recognizes three varieties of cases, as follows:

1. The urticaria is of alimentary origin and appears regularly, immediately or soon after the ingestion of such foods as milk, eggs or chocolate; some months or years later tolerance sets in and the eruption no longer occurs.

2. In these cases, which develop between the age of six and fifteen months, the urticaria appears at irregular intervals, without relation to any particular food, and lasts from a few days to three weeks in each attack. Moderate digestive disturbances, with loose, malodorous, whitish stools and constipation or diarrhea, may precede, accompany or follow the eruption. This variety may be regarded as of digestive origin, and rather often passes off at the end of the third or fourth year.

3. The third class of cases is characterized by the sudden appearance of the eruption, which is transitory and is unattended with any apparent digestive disturbance. Often this idiopathic variety, appears only at long intervals and causes the patient little inconvenience. Disorders of hepatic origin may precede, accompany or follow the urticaria of childhood, and are manifested in bilious vomiting, diarrhea, more or less colorless stools, or sometimes cyclic vomiting.

In the treatment of urticaria the author recommends ingestion of a mixture of twenty-five per cent. meat peptone, twenty-five grams; neutral glycerin, ten grams, and syrup of orange, enough to make one hundred and twenty-five mils. One teaspoonful of this is given by mouth one-half to one hour before each meal as long as the eruption persists, or indefinitely for prophylactic purposes in frequently recurring cases. Sometimes better results are obtained by using the special peptones from egg white or yolk or from the casein of milk. Results are not constant, however, and better effects may unexpectedly be obtained with the indifferent meat peptone than with the specific peptones for egg or milk cases. The exact reason for these individual discrepancies is as yet unknown.

Urobilin in Feces and Urine of the Newborn.—Lotte Goldschmidt-Schulhoff and A. Adler (*Zentralblatt für Gynakologie*, July 12, 1924), conclude that the excretion of urobilin in the newborn is independent of any existing or absent tissue icterus, but that it does speak in favor of a functional injury of the liver. Normally and physiologically urobilin is to be found neither in the urine nor in the feces, but the presence of pigment indicates a tendency toward icterus, to which only any factor causing an icterus is necessary and the nature and point of attack of which is still unknown. The same condition exists in regard to the bilirubin content of the blood and feces and to the biliary acid content of the urine. In this case there is also no relationship to the occurrence of an icterus. The important factor in icterus is not to be sought actually in the occurrence of the tissue icterus, which is only a symptom of the pathological condition, but rather in the metabolic conditions of the pigment in the organism of the newborn, any deviation of which from the normal indicates a disturbance in the activity of the liver cells. The liver alone should be considered as the site of origin of the urobilin in the newborn.

Facial Phenomenon in Children.—Stanley G. Graham and Grace H. Anderson (*Lancet*, June 28, 1924) found that 1,723 children between the ages of five and eighteen years, twenty-nine per cent. showed a positive facial phenomenon. A positive facial phenomenon in older children is not to be considered as evidence of latent tetany, because, a, there is no increased electrical excitability; b, no other sign of tetany and no history of previous tetany could be obtained in any of the cases; c, the sign varies from day to day; d, the calcium and phosphorus content of the serum were not found to be altered; e, the sign was found most frequently among a class of children in whom tetany rarely occurs; f, treatment with calcium chloride failed to produce a complete disappearance of the sign, as it does in cases of undoubted tetany. The fact that the sign occurred as frequently among healthy as among ailing children, and its common occurrence in the children brought up under the best social conditions, led the authors to attach little significance to its presence except as a possible indication of a neurotic disposition.

Meningeal Hemorrhages in the Newborn and Their Remote Consequences.—Alfred Gordon (*American Journal of Diseases of Children*, April, 1924) draws the following conclusions: The cause of meningeal hemorrhage is, principally, the tearing of the membranes due to their overstretching, which leads to rupture of the bloodvessels. To produce a tear, there must be great cranial stress. Since the latter is frequently the result of protracted, difficult labor, with instrumental delivery, the obstetrician should bear in mind that the force used in the application of forceps should not be excessive, or should not be applied to the wrong diameter of the head, as the anteroposterior diameter. Forceps are useful, but they may also be responsible for injuries in the fetus leading to consequences which have a direct bearing on the later physical and mental development of the child.

The preventive aspect lies in the consideration of all forces that are liable to lead to tearing of the meninges and the bloodvessels. Wrong presentation and position of the fetus and other causes of difficult labor, such as prolapse of the umbilical cord, the use of instruments or various manipulations in the delivery of the fetus, are all important factors of danger.

With a certain degree of possible errors, supratentorial hemorrhages, generally, present a somewhat different clinical picture from the infratentorial type. In the former, the blood spreads over the cerebral hemispheres; in the latter, over the cerebellar hemispheres and into the medulla. Consequently, in the former at birth, one finds a bulging fontanelle, and a group of nervous phenomena, such as insomnia and great restlessness and convulsive seizures, with a continuation of the condition. In the latter, there is considerable depression, apathy, somnolence, early cyanosis, vasomotor and respiratory manifestations and rigidity of the neck muscles.

Anatomically, in infratentorial cases lumbar puncture may be of considerable benefit. In the supratentorial cases lumbar puncture does not avail much. Surgical therapy is almost the only issue. Early craniotomy is directly indicated, and favorable results are to be expected only when the operation is performed within a few days after birth. In all cases indicating increased intracranial pressure at birth, lumbar puncture should be resorted to at once, before a definite localizing diagnosis is made.

Effect of Heat Treatment of Milk Feedings on the Mineral Metabolism of Infants.—Amy L. Daniels and Genevieve Stearns (*Journal of Biological Chemistry*, August, 1924), studied the mineral balance on boy babies varying in age from three to seven months, with the following results:

In certain instances babies who were holding their weight on given milk mixtures when pasteurized by the "hold" method, gained when the mixtures were quickly boiled, no other change being made. The calcium and phosphorus retention in infants fed quickly boiled milk mixtures was considerably greater than it was when the milk mixtures were pasteurized. The fecal calcium and phosphorus were greater during the period when pasteurized milk feedings were given, indicating that the longer heat treatment of milk results in a decrease in the availability of the phosphorus and calcium in the milk mixtures. There appears to be some relation between the calcium, phosphorus, and nitrogen retentions. It seems probable that the calcium needs of children are very largely determined by their skeletal development. In determining the calcium needs of normal children, it would seem more nearly fitting to include only those who are up to standard in weight, or to determine the calcium needs on the basis of the theoretical weight of the infants. It is probable that a baby fed pasteurized milk over a long period of time is not receiving a sufficient amount of calcium for his growth needs.

Medicolegal Notes.

FOUNDATION FOR MEDICAL EXPERT'S OPINION

A medical witness in a personal injury case was asked if his experience had been sufficient for him to form an opinion as to the effect a concussion of the brain could have upon a man who had had an injury to the brain and thereafter suffered dizziness and loss of memory. To this question objection was made that "it lets the witness judge, and is not an opinion." The New Jersey Court of Errors and Appeals held, Stefanacci v. Borden's Farms Products Co., 125 Atl. 129, that the question was properly admitted. The court said: "Whether the witness qualified as an expert was of course a court question but the extent to which his knowledge may permit him to speak on matters within the purview of his science is a medical question on which he and those alike qualified could best express an opinion. It is a form of inquiry frequently met with in the trial of causes of this nature, and seeks to elicit from the witness the possibilities in the science itself or the extent of his own attainments in the science. There are bounds to medical knowledge, and it it not improper that we should ascertain those bounds from him whose training and experience qualify him to speak."

It was also held proper to admit the doctor's affirmative answer to the question if his reading and study entered into the opinion he had given. The court said: "It is by reading and study, as well as by experience, that the expert becomes such. To deny him the right to use these, when called as an expert witness, would be to frustrate the whole theory upon which the trained mind is admitted to express opinions in a court of justice."

EVIDENCE SHOWING THAT ACCIDENT WAS THE SUPERINDUCING CAUSE OF DEATH

In a proceeding for compensation for the death of a meter reader, it was held, Guyer vs. Equitable Gas Co., Pennsylvania Supreme Court, 123 Atl. 590, that the testimony of a customer of the gas company that deceased in the performance of his duty had entered her home looking pale and saying he had just slipped and hurt himself, pointing to his back, corroborated by the circumstances, including the fact that he subsequently suffered severe pain accompanied by frequent vomiting, which continued until his death, was sufficient to support the finding of an accident sustained in the course of the employment.

"The autopsy disclosed a diseased condition of the pancreas known as a cyst, which had been ruptured, as had also surrounding bloodvessels, resulting in the escape of large quantities of blood into the abdominal cavity. The family doctor was present at the autopsy and, as a witness, expressed the opinion that the fall had caused the rupture of bloodvessels, which, in turn, had caused the rupture of the cyst and death, and but for the accident Guyer might have lived for years, notwithstanding the diseased pancreas. Other doctors expressed the opinion that the rupture of the cyst, which all agreed was the immediate cause of death, was from natural causes wholly apart from the accident.

"The testimony of the family doctor was competent, and, if credited, which was for the referee and compensation Board, justified the finding that the accident was the superinducing cause of death; if so, the fact that the diseased condition of the pancreas might ultimately have caused death is no defense. There being legal evidence to support the findings, they cannot be disturbed either in the lower court or an appeal."

SUNSTROKE SUCH AS ANY ONE IS LIABLE TO NOT HELD AS ACCIDENT ARISING OUT OF EMPLOYMENT

Sunstroke or heat stroke has often been held to be an accident, both under the provisions of insurance policies and of Workmen's Compensation Acts; but sunstroke suffered by a log hauler while driving a team along a highway was held by the Indiana Appellate Court, Townsend & Freeman Co. v. Taggart, 142 N. E. 657, not to be an accident arising out of his employment, all travelers along the highway at that particular time being exposed to the same danger.

VALIDITY OF DYING DECLARATIONS

The Georgia Supreme Court, in a murder case, Benton vs. State, 122 S. E. 775, held that it is not necessary for the state, introducing in evidence dying declarations of the deceased, to show affirmatively that the deceased said he was in a dying condition in order to admit proof of his declarations, if in point of fact he was in articulo mortis, and the circumstances were such that he must have known that he was in a dying condition. Consciousness of his condition may be inferred from the nature of the wound and other circumstances. The fact that the statements of the deceased were made in response to questions asked him by another does not render such statements inadmissible. This fact may affect the weight to be given to the statements, but not their admissibility.

X RAY PHOTOGRAPHS OF THIRD PERSONS NOT ADMISSIBLE IN PERSONAL INJURY CASE

In a personal injury case the New Jersey Court of Errors and Appeals, Eggert v. Binder, 125 Atl. 106, held that it was proper to refuse the defendants offer to show x ray plates taken by a witness of other persons than the plaintiff, since they had nothing to do with the case on trial.

HEART DISEASE HELD NOT RESULT OF ACCIDENT

In proceedings for compensation for death from heart disease, occurring nineteen days after helping in the handling of large stones required in bridge construction work, one doctor testified that the overexertion caused the condition resulting in the death. Two other physicians said it "could" have been produced by the undue strain, but not that it "probably" resulted from this cause. The expert for the defendant gave evidence directly to the contrary. This raised a question of fact to be passed upon primarily by the referee and the Compensation Board subject to review by the common pleas. The dispute was decided adversely to the claimant, and the Pennsylvania Supreme Court held, Thomas v. State Workman's Insurance Fund, 124 Atl. 490, that the conclusion reached would not be set aside by that court, since it did not appear that relevant matters essential to a proper determination of the controversy had not been sufficiently inquired into. There being testimony showing weakened organic condition, which possibly might have been aggravated, the burden was on the claimant to show that the alleged accident was the probable cause of the death.

NO CAUSAL CONNECTION BETWEEN INJURY TO SIDE AND SUBSEQUENT PNEUMONIA

The Illinois Supreme Court holds, Perry County Coal Corp. v. Industrial Commission, 311 Ill., 206, 142 N. E. 453, that there was no causal connection between an injury to a mine employee by the right side of his chest coming into contact with a jack pipe, after which he continued at work about three weeks, and pneumonia resulting from a cold contracted while taking a bath, and he was not entitled to claim compensation.

The Treatment of Fractures

SIR W. ARBUTHNOT LANE, M.B., M.S., F.R.C.S.
London

I propose to consider the changes that have taken place in the method of treatment of simple fractures since I started operating on them in 1894, a period of more than thirty years.

At that time the treatment of simple fractures was a disgrace to surgery. While that statement might be somewhat modified I believe that at the present time no branch of surgery is as unsatisfactory as this is and that a large proportion of the bad results of treatment are due in part to ignorance and in part to a want of skill on the part of those into whose hands they were unfortunate enough to fall.

The average student while in the wards sees only a small number of cases of fracture and he soon discovers that the views held, and the methods and the results of treatment adopted by his several surgical teachers, vary within wide limits. The excellent radiography done at the big London or other large general hospitals enables him, however, to recognize the character of the fractures, and he must form his own opinion on the relative advantages of the several methods of treatment which he sees adopted.

When he goes into practice he rarely has a case of fracture under his care and he soon realizes the anxiety and risk that its treatment involves him in. He may experience great trouble in the accurate diagnosis of a fracture since it is often impossible owing to difficulties of transport to obtain a radiogram in the case of fracture of the leg, and many of the radiographers and apparatus in country districts are not infrequently unable to produce perfect radiograms. A poor radiogram is often more misleading than none at all. The bad results of treatment both functional and esthetic are very obvious and as excellent radiograms can subsequently be easily obtained by the patient they may readily bring the medical attendant into a court of law, and may expose him to great financial loss and professional discredit. It is not generally recognized how many actions for damages are stopped by the tactful advice of the consultant or by a compromise of a financial nature.

The most important law I ever formulated is that *"the skeleton represents the crystallization of lines of force."* It is upon the knowledge of this law that the scientific treatment of fractures depends. The same law applies equally to every soft structure in the body and perhaps more effectually and obviously to the several portions of the gastrointestinal tract sufficiently to impose on the community about all the diseases of civilization.

Few surgeons appear to have sufficient mechanical knowledge and skill to deal effectually with fractures by operative procedures. As the risk of a possible unsuccessful result is so manifest it is very advisable that any medical man who is asked to treat a fracture should call another into consultation and he might with advantage choose an opponent. In this way he will materially safeguard his interests. In any case he should join a medical defence society when he starts in practice.

In operations on simple fractures the operator may experience great difficulty in bringing the fragments into accurate continuity, especially when two bones are involved, or when there is much comminution. Even when the fragments are placed in apposition, too short, a plate may be employed with an insufficient number of screws, or the plate may be placed in an unsuitable position, or the precautions taken may not be sufficient to ensure perfect asepsis.

It is no longer necessary to urge the wisdom of operating on simple fractures when the conditions which I put forward in my paper (1) in 1894 exist, the chief of which is the necessity for restoring perfect continuity of the fragments of a broken bone or bones by operation when it is of vital importance to the patient that the normal function of the skeleton has to be restored, assuming that it is not possible to obtain this result if other means have proved ineffectual. This applies to the long bones of the leg even more than it does to the rest of the skeleton since they have to transmit the weight of the body.

The somewhat abrupt change in the manner in which the operative treatment of simple fractures was regarded by the profession was due to the wise action of the British Medical Association on the initiative of Sir Victor Horsley, the then president of the Surgical Section, at the meeting of the British Medical Association in London in 1910, in appointing and generously financing a committee to investigate the result of the various methods of treatment and in printing their full report as a separate publication. It was entitled, The Report of the Committee on the Treatment of Simple Fractures. It contained a full and accurate description of the methods and results of the treatment of fractures in the several parts of the world.

Copyright, 1925, by A. R. Elliott Publishing Company.

The committee comprised sixteen members who took part in the investigation on which they expended much time and trouble. The conclusions which they arrived at fully bore out the accuracy of my views. The committee was appointed in February, 1911, and the report was published in November, 1912.

This is, I believe, the only occasion on which the British Medical Association has taken such thorough and effectual measures to arrive at the truth in order to inform the medical profession on a subject which had long been discussed with so much violence and acrimony. The change in the attitude of surgeons to operative measures was at first followed by disastrous results, especially in America, where fractures were operated on by a large number of medical men whose experience and skill varied within wide limits. The failures that resulted from such indiscriminate operations were due to insufficient aseptic precautions as well as to lack of mechanical knowledge and of aseptic precautions. This brought about a reaction against operation, the procedure being held responsible and not the want of familiarity of the operators with the details necessary to insure successful results.

Many surgeons, hoping to obtain better results, attempted to improve on the simple methods which I employed, and which I have used with uninterrupted success since. They made more complicated steel plates or they used plates made of bone, they devised elaborate and intricate screws and screw drivers, drills, forceps for grasping the fragments and retaining them in apposition, and many other modifications, all of which rendered more difficult a procedure which in principle is perfectly simple, but which may be made most difficult and unnecessarily complex in its application.

The war produced a great change in the treatment of fractures by operation. Many of those surgeons who had been most actively opposed to operations on simple fractures did not hesitate to put plates and screws into the fragments of the broken bones in compound fractures usually produced by projectiles with the most disastrous results. It was quite a long time before the folly of this procedure was realized and a stop was put to this practice.

Even when the wound had healed or was apparently quiescent the introduction of such large foreign bodies as plates and screws not infrequently resulted in the renewed activity in the growth of septic organisms which had lain dormant in the bone and in the soft parts so that disaster followed such operative procedures only too frequently. It was a long time before this complication was recognized and dealt with, but finally the results obtained with suitable precautions were excellent.

With all this experience some surgeons still continue to secure the fragments of bone in recent compound fractures by means of plates and screws with the same most unfortunate results.

Every new procedure would appear to involve necessarily much damage and loss of life to the community, till the principles of the treatment and their application have been thoroughly grasped by surgeons generally. The use of steel screws has been objected to on the ground that they produce a rarefying osteitis, and that they have to be removed in consequence. This is due to imperfect asepsis and results only when the aseptic precautions employed by surgeons are insufficient. That this does not occur if enough care is taken is demonstrated by a large number of radiograms. It is perhaps not sufficiently recognized that the moderate degree of asepsis which is employed in operations generally throughout the body is quite inadequate for procedures involving the burying in the tissues of a quantity of metal. This only too readily affords a nidus and a medium for the growth of organisms, which do not exist in the wound in sufficient quantity to produce trouble without the presence of the foreign body.

Great advances were made during and since the war in the treatment of severe compound fractures of long bones especially, and much was done to improve methods of traction in simple fractures, by which the resistance offered to the apposition of fragments by the shortening up of the soft parts by hemorrhage and inflammation can be gradually overcome.

The most effectual method of treatment of simple fractures of the shafts of the long bones of the leg in which operative interference is not called for is by forcible extension usually under an anesthetic followed by the use of an ambulatory splint. The splint must be so constructed that while the fragments are being constantly extended the patient is able to lead an active life, moving the joints of the damaged limb with perfect freedom. In this way not only does the patient avoid stiffness of the joints and muscles which accompanies the ordinary methods of treatment but the formation of callus is hastened by the free circulation of blood through the limb. This splint can also be employed with great advantage after the fragments have been secured by means of plates and screws.

In the case of fractures of the shaft of the long bones of the leg this principle is carried out in an ideal manner by the extension apparatus devised by Mr. Hoefftcke with which you are probably familiar.

The principle involved of replacement of fragments by extension, the continued exercise of traction by some form of apparatus and the free spontaneous functioning of the muscles, soft parts and joints in the vicinity of the fracture, is that which governs the treatment of all simple and compound fractures. How often does one see a patient incapacitated for months and sometimes permanently by the limited range of movement of the joints in the vicinity of a fracture due to their having been left in one position for a long period. This complication is perhaps most serious in the case of a knee which has been allowed to become fixed in a flexed position.

In such cases of simple fracture in which the necessity for perfect function cannot be met because of inaccurate apposition of fragments operation is called for. In the case of malunion following compound fractures, only when the operator has every reason to suppose that the tissues have become freed from the presence of any organisms which existed in the original wound should surgical measures be undertaken with the object of restoring axial continuity of fragments. Such operations are often most difficult and may make a great demand on the knowledge, judgment and skill of the operator. This is particularly the case when both bones of the forearm or leg are involved. Grafts of bones should be used freely to fill up any gaps that may remain between the frag-

ments. Though it should be borne in mind that quite a considerable interval can be readily filled in by recrystallization of bone, along the line of force, great pains should be taken to secure them in position and immobilize them. The great advantage gained by the skilful employment of bone grafts is illustrated by the remarkable work which was done by Mr. Gillies and the other surgeons and dentists at the Queen's Hospital, Sidcup. The methods devised and adopted by those men form a new era in the treatment not only of the damage produced by projectiles but also of the various deformities and fractures of the bones of the face in civil life. The published works of Gillies and Pickerill contain full descriptions and illustrations of the various operative procedures requisite for these conditions.

Splint Treatment of Fracture of the Neck of Femur and Hip Disease

E. H. BRADFORD, M.D.
Canton, Mass.

In the NEW YORK MEDICAL JOURNAL of November 22, 1919, a case was reported of unquestioned fracture of the neck of the femur in a woman of sixty-three years, treated by an abduction and traction splint from the first, without other fixation, with ambulatory treatment at an early date. The result was remarkable; the complete reestablishment of motion at the affected hip, without shortening or deformity, and the return to normal activity in six months. The case was shown before three medical societies, Suffolk and Norfolk South Districts of the Massachusetts Medical Society, and at the meeting of the American Medical Association in Boston, before the surgical section, where the definiteness of the cure was verified by physicians and surgical experts.

Other practitioners[1] have employed this method first adopted at the Massachusetts Hospital School and with satisfactory results. The following illustrative cases are reported:

CASE I.—Mrs. F., aged seventy-seven; gouty diathesis; extremely stout; wife of physician. The fracture occurred January 28, 1923; immediate extension, weights and pulley were employed. On the third day an x ray was taken and an abduction traction splint applied. On the fifteenth day there was no pain. During the fifth week a walking frame was used for she could not use crutches. The seventh week, a high sole, walking frame and bearing some weight. In eleven and one half weeks she was walking freely with the aid of a cane and without apparatus. The fourth month she was going up and down stairs without assistance and taking long automobile rides. The last condition showed no limp; no shortening; no limitation of motion. Symptoms, diagnosis and treatment were closely followed by seven physician friends of the family, five of whom were familiar with the use of the splint in other cases. (Figs. 1 and 2).

Fig. 1.—Case I.

Fig. 2.—Case I.

CASE II.—Mrs. N., aged fifty years. Date of fracture, March, 1918. Weight and pulley traction were used about three weeks, when the traction abduction splint was applied and the patient was allowed to move around freely in bed. She began to be up in her bedroom at the beginning of the fifth week from the date of fracture, and continued every day thereafter. She went down stairs at the beginning of the tenth week. The splint was removed three months after the injury. In the fifteenth week she discarded her crutches. (Figs. 3, 4, 5 and 6.)

The advantages of this method of treatment are evident. Not only is the patient relieved from the uncomfortable confinement of plaster of Paris fixation, but it may be believed that the freedom from plaster of Paris fixation aids in bone union. Before the introduction of plaster of Paris fixation, nonunion was little feared and bony union was to be expected with joint stiffness, some shortening and permanent disability. Since the use of plaster of Paris, however, nonunion is mentioned by several surgical authorities, with prolonged treatment by fixation, bone plating, insertion of a nail or other operative procedures, which are not infrequently unsuccessfully employed, inflicting permanent disability.

The plaster splint is known to cause muscular atrophy, unhealthy skin action, increased radiability of bone and presumably delayed bone formation. The splint ambulatory treatment here recom-

[1]References: Dr. John P. Gifford, Randolph, Vt.; Dr. Michael Barrett, Brockton, Mass.; Dr. Herbert E. Fernald, Cohasset, Mass.; Dr. William O. Faxon, Stoughton, Mass.; Dr. Walter A. Griffin, Sharon, Mass.; Dr. Roland Hammond, Providence, R. I.

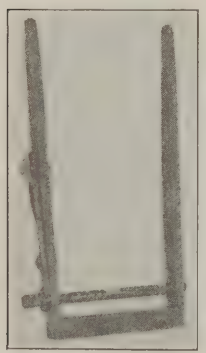

FIG. 11. — Showing ratchet attachment.

mended has the advantage of steadying the broken fragments, pulling them into their proper position and counteracting the pull of the adductor muscles. It gives sufficient fixation of the joint between the pelvis and the femur. It gives a minimum of constriction and resulting atrophy. It prevents the contraction of periarticular ligaments formed in the original accident, and allows gradual motion when it seems desirable to begin joint mobility.

This method of treatment was suggested for fracture of the neck of the femur by its satisfactory employment in cases of hip disease, where steadying the affected parts, counteraction of muscular spasm in the muscles around the hip, and protracted ambulatory treatment for a long period, are all desirable. Satisfactory results have been obtained in the treatment of many cases of hip disease by this method at the Massachusetts Hospital School, histories of which are recorded. (Fig. 7.)

The Massachusetts Hospital School is a state institution, primarily established as a school in 1908 for the care and education of crippled and deformed children who are physically unable to attend public day schools in competition with normal children. Soon after the opening of the school it became apparent that hospital facilities should be provided, and an infirmary department was established, which has now been in operation fourteen years. Of the 1,201 cases thus far received, there have been approximately two hundred cases of hip disease in various stages with deformity and partial cure, making ambulatory and fresh air treatment desirable. The cases most successfully treated were naturally those for whom the splint treatment had been begun at an early stage, and in whom bone ankylosis had not already been established. From these facts it would appear that mechanical treatment of hip joint lesions as here described can be confidently recommended to the profession.

Surgeons may be deterred from the use of the splint through unfamiliarity with mechanical aids. The splint itself, however, is a simple one, being a modification of the well known Thomas knee splint, which became familiarly known in the late war, but with the addition of adduction and traction adjustments. The splint (Fig. 8) consists of two steel rods longer than the affected limb, connected below by a flat bar forged out of the uprights or welded to them. The rods are attached above by a ring (Fig. 9) opened in front and obliquely placed upon the rods so as to fit the buttock from the tuber ischii to above the great trochanter. Attached to the ring near the top of the inner rod is welded a bent steel rod which passes above the symphysis pubis and under the perineum of the well side. This abduction arm (Fig. 10) should

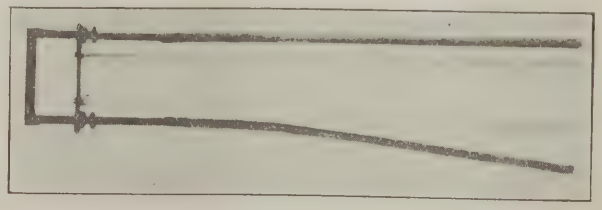

FIG. 12.—Movable transverse rod.

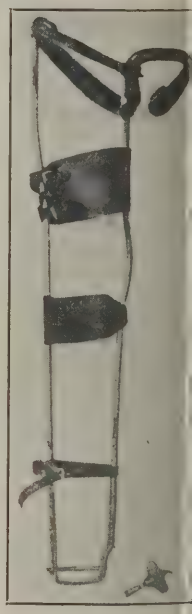

FIG. 8.—The splint

be long enough so that the end does not press into the buttock when the patient is seated. The upper rings are padded and covered with leather, and if properly shaped are not soiled by the feces or urine. Traction is furnished by means of adhesive plaster straps applied to the limb in the same way as for traction with weight and pulley. Just above the bar which joins the two uprights at the bottom, there is a windlass and ratchet attachment (Fig. 11) to which webbing straps attached to the adhesive plaster may be secured and by means of the windlass the necessary amount of traction obtained. The splint acts as a perineal crutch which can be adjusted to obtain as much abduction as may be desired. Circular straps of leather, canvas or convenient material may be employed to steady the limb. In place of the windlass and ratchet a simpler and cheaper traction attachment may be obtained by a movable transverse rod (Fig. 12) which may be adjusted and firmly fixed by means of nuts and threads at the lower end of the two upright rods. This apparatus requires less skill in application than is necessary in the use of plaster of Paris which is more cumbersome and confining to the patient, and offers less promise of a satisfactory result.

The Treatment That Gives Best End Results in Fractures About the Elbow Joint*

DAVID H. ORGEL, M.D.,
New York

The purpose of this paper is not a description in detail of the mechanics and the varieties of fractures of the elbow joint, but a discussion of the methods whereby the best end results are obtained. The elbow joint is more frequently injured in children than in adults and a study of development must be made to note the marked difference between the nature and extent of injuries in children and in adults. Before the twelfth year an x ray of a child's elbow will show the bony parts separate and distinct from one another: 1, shaft of humerus; 2, shaft of ulna; 3, shaft of radius; 4, ulna head; 5, capitulum; 6, trochlea; 7, olecranon; 8, external condyle; 9, internal condyle—a broken up joint without injury.

The difference, however, is not so great when we consider that the cartilage is as strong as the bone of the adult and the ligaments stronger; so that in an injury, the part giving way is the weakest—the bone in most cases. In the treatment the same method is used in children and adults, the end results being the same.

We agree with Ashhurst (1) and Neuhof (2) in comparing end results—"adding but one addition to their perfect result—"one in which the full and normal range of motion" and the presence of the normal carrying angle are the sequel of the treatment.

Fractures around the elbow joint can be classified, although anatomically not accurate, as suggested by Neuhof (2): 1, supracondylar (diacondylar); 2, internal condyle (including trochlea and epitrochlea); 3, external condyle (including capitulum); 4, head of radius, and 5, olecranon. The treatment in all, except the last, is best in the position of hyperflexion (extreme acute flexion). In considering the treatment, we must adopt that which will give us the best functional result and commensurate with the time required for immobilization of the same.

Supracondylar or diacondylar fractures are most frequent; about seventy-five per cent of all fractures around the elbow joint, and the description of the treatment of this will cover all other forms except olecranon. In supracondylar fractures we find a backward and upward displacement of the lower fragment. Here is where most men differ in treatment, whether by acute flexion, right angles or extension, in order to keep the fragments in position. This difference of opinion is due to the fact, as was pointed out by Lusk (3), that the fragments are not originally completely reduced. This can only be done by overextension, then suddenly flexing the elbow joint and keeping it in the hyperflexed position where the triceps will hold the fragments in alignment. Other authorities, as Keene (4), Scudder (5), Warbasse (6), Hitzrot (7), Gask and Wilson (8) and Speed (9) are undetermined as to the best method. It must, however, be admitted that occasionally a case will be met with in which in spite of overextension and acute flexion we find that the fragments are not in alignment, and only in the right angle position can they be kept in apposition. Radiographs should be taken before and after to see if the fragments are in proper position and to determine the best method of immobilization. If possible it may be best to replace the fragment directly under the fluoroscope.

Internal condyle.—This is the most disabling of all fractures around the elbow joint, on account of the loss of continuity of humerus and ulna and the loss of function of the arm. The most important element in this fracture is the pulling upward of the fragment and the loss of the carrying angle. In a position of acute flexion the broken internal condyle is kept in position by the weight of the forearm, and the ulna and triceps prevent its displacement backward. The fragments cannot be rotated when the flexors are relaxed.

External condyle.—The line of fracture usually takes in the joint. The disability, cubitus varus, is found in this fracture. If the parts are first placed in position of acute or hyperflexion, by which the external condyle is held in its normal position by the tense triceps, there is no tendency to this deformity.

* Read before Alumni Association of City Hospital, May 21, 1924.

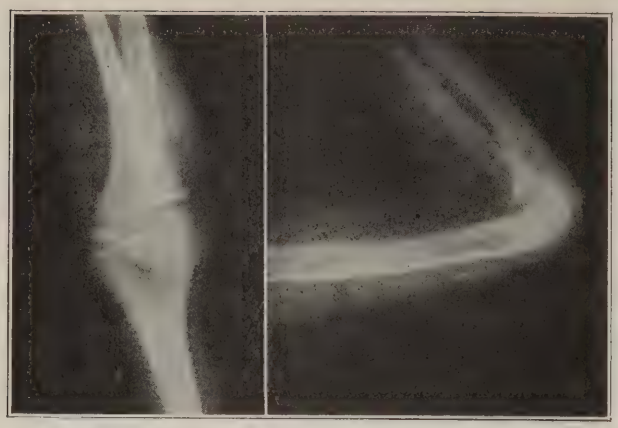

Fig. 1.—Case I.

If, however, an internal or anterior angular splint (Keen-Stimson), is used, it does not prevent the anterior and downward displacement of the external condyle. Complete extension is irksome to the patient; it tends to pull the condyle downward, and is difficult to maintain the carrying angle. Most authorities admit (Cotton, Scudder, Ashhurst, Da-

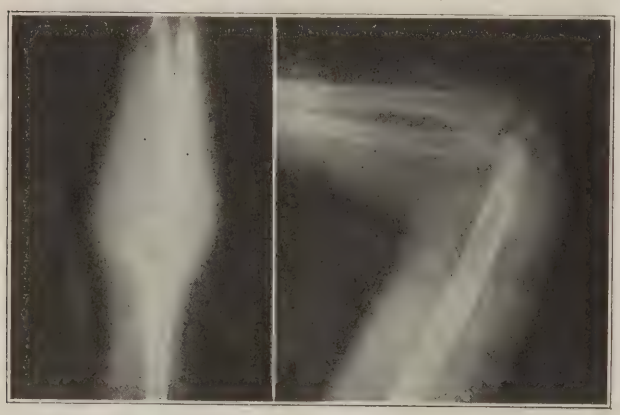

Fig. 2.—Case II.

Costa, Brewer and others) that the position of acute flexion or hyperflexion gives best results.

The most important points to be considered in any treatment are the retention of flexion, extension and the carrying angle. From a large collection of fractures around the elbow joint and sifting the end results, we have come to the conclusion that the

Fig. 3.—Case IV.

position of hyperflexion has given the best results.

The next question presenting itself is how long shall the elbow be kept in this position. Opinions are still divided. Most authorities agree with Jones (10), Speed (9), Ashhurst (1), Gask and Wilson (8), Warbasse (6), Hitzrot (73, Keene (4) and Scudder (5) in keeping the elbow immobilized for about three to four weeks. We have found, con-

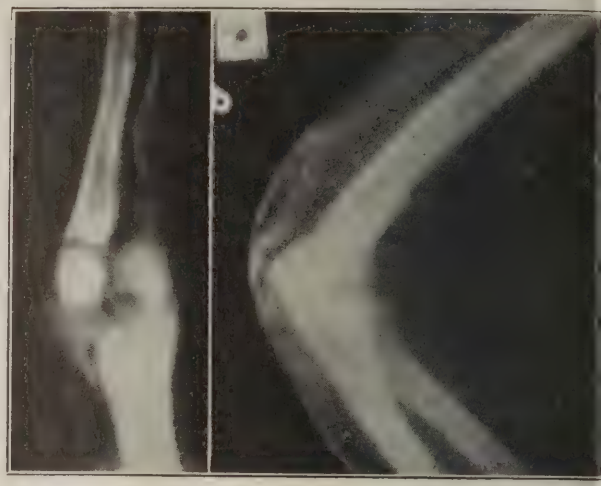

Fig. 4.—Case VII.

firming results of Neuhof and Wolf (2), that in most cases the best results are obtained by keeping the fragments immobilized for ten days to two weeks and thereafter gently, by massage and passive motion, to flex and extend the arm. After the third week if extension is not complete, help the same along by baking. The massage and passive motion must be gentle so long as the spasm of the muscles continues.

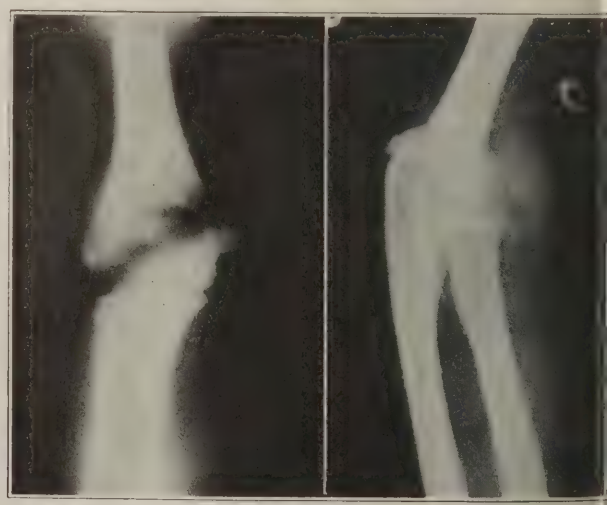

Fig. 5.—Case VIII.

Whether we use for immobilization plaster splints, as recommended by Hitzrot, or adhesive plaster, does not affect the result as long as the fragments are properly reduced by hyperextension and the elbow is in hyperflexion, care being taken not to compress the radial artery; and the forearm in supination with the wrist suspended from the neck. The

triceps act here as a natural splint, and whatever we use is only an additional support.

The end results, in my experience, bear no comparison to those treated by other methods. All my cases except one have been treated by acute flexion and the results have been uniformly a perfect result as far as functional use is concerned.

Olecranon fracture.—Extension has been found the best method of coaptating the broken fragments —and immobilization in this position. When, however, the elbow is included in the fracture we use acute flexion, and after ten days extension.

Fractures of the head of the radius, when fragments are in position, are treated the same as elbow fractures. Occasionally we find it impossible to replace the head of the radius, the head being rotated by flexion, and we may have to remove the head of the radius before a perfect result can be obtained.

The following are examples of some of the worst cases and the röntgenograms represent the position of the fractured parts when applying acute flexion:

Case I.—Patient R. B., fourteen years of age. Fig. 1, A, shows comminuted fracture of the lower end of humerus; B shows the arm put up in partial flexion and the fragments held in position.

Case II.—Patient S. G., eleven years of age. Fig. 2, A, shows diacondylar fracture; B shows arm in partial flexion.

Case IV.—Patient I. K., eleven years of age. Fig. 3, A, shows supracondylar fracture; B, acute flexion.

Case VII.—Patient W. S., eighteen years of age. Fig. 4 shows fracture of internal condyle, epicondyle and tip of olecranon.

Case VIII.—Patient M. U., twenty-two years of age. Fig. 5 shows fracture of internal condyle and tip of olecranon.

CONCLUSIONS

In all fractures around the elbow joint, except the olecranon, the most perfect results are obtained with the elbow in acute flexion (extreme) and a minimum immobilization period. Whether the patients are children or adults makes little difference in the results.

Massage in Surgical Cases

WELLER VAN HOOK, M.D.
Chicago

The effect of centripetal massage movements, the passes predominantly moving towards the heart, is to favor the passage of the lymph already in the lymph vessels toward the centre of the body, and to cause fluids lying in the lymph spaces to pass into the vessels. The good effect of this movement of fluids is recognized and unquestioned, and the art of massage owes much of its popularity to the acceptance of this principle.

But in surgical practice there is another need met by massage that is of equal importance—the need of resolving or removing fields or areas of deep, pronounced, sluggish and often painful infiltration in the connective tissue. Such boggy masses are of the utmost frequency of occurrence. Many times they form as the result of inflammations, just as they also follow injury. Only very young and vigorous persons throw off quickly the tendency of such masses to remain, assuming the character of chronicity. Their passing away depends on the maintenance and the heightening of the flow in the lymphatic vessels and the restoration of normal conditions in the cellular tissue. Men often speak of the patient's own physiological activities as adequate in emptying the lymph spaces and vessels. But I am confident that it is only in the case of young and vigorous persons that strictly unaided action gives us those prompt, full results that alone are of the highest value in restoring normality without scars.

Where these conditions are not supplied massage is of the greatest assistance. For it not only empties the vessels, but, properly administered, it also supplies to the cellular tissues and to the lymphatic vessels that gentle traumatism so greatly needed to rouse all the parts to resume an aggressive vital activity.

The skilled masseur, in practice, first reduces by centripetal movements the quantity of lymph in the tissues and the vessels; then he carefully proceeds to the treatment of indurations and infiltrations. And it is perhaps the most triumphant daily success of the masseur to break down and cause to disappear such deposits. If they are not thus caused to disappear the amount of scar tissue produced is eventually much increased, for connective tissue tends to grow into such deposits. And the induration and the contracture result in subsequent atrophy of the tissues. Even the bone becomes porotic, less stable and less resistant largely on account of diminished activity. It is well known that cicatricial tissue that has thus grown into tendon sheaths, aponeuroses and joint capsules or ligaments renders the affected tissues harder, stiffer, less supple and obedient to the will of the patient who so urgently needs mobility, flexibility and strength.

The practice of massage in fractures is of the utmost importance, and yet it seems to me its possibilities and practical uses are not recognized except

rarely. Immediately upon the setting of a fracture provision should be made for massage, if it is at all possible. For example, in all the cases of fractures of the lower extremity in which the chief reliance is light fixation or extension with some sort of splint, provision for massage should be made at the outset. This means that the field of the fracture should be kept easy of access and that the fixation of the parts by extension and by splints shall be adequate. All fractures are attended with some vascular rupture. Capillaries, veins, arterioles or even arteries may be torn. The extravasation of blood, evidenced by the clinical demonstration of fluid or much more frequently of coagulated blood, gives rise to socalled black and blue areas showing through the skin, to tight distention of the soft tissues with palpable masses of coagula and to shadows visible in the röntgenograms.

The reaction produced in response to the trauma adds an exaggerated quantity of lymph which still further distends the soft parts of the limb. Under these circumstances the use of massage is most desirable, the only exceptions being those cases in which immobilization may be compromised by the manipulations with possible displacement of fragments or where open wounds might become infected. Both these difficulties the skilled and eagerly interested surgeon almost always will be able to overcome. The masseur must be content for the first few days with modest progress in the removal of débris and with the appropriate necessary training of the tissues to tolerate the slight traumatism that is so urgently needed.

When the patient and his tissues are seasoned in this very simple manner very rapid improvement of the extremity is almost certain to occur. For the masseur makes a great effort to empty all vessels and cavities communicating with them. Naturally at the same time the fluid part of the extravasated blood is carried off, while the particulate, insoluble portion is largely taken up by phagocytes and carried off bodily. The observation of the process is interesting to the onlooker. The circumference of the limb, the tightness or tension of the tissues and the mass of palpable deposits are diminished rapidly, leaving the limb of much more normal appearance and resistance to palpation. The color of such a limb becomes much more satisfactory and the normal movement of the blood and lymph gratifyingly free. The edema disappears as part of the infiltration, and the tenderness of the extremity is almost wholly removed.

One cannot escape the conviction that the minute repair processes in the tissues about the damaged bone ends proceed under these conditions with greatly heightened swiftness and effectiveness. And the removal of dead tissues not needed but acting as foreign matter is of vital importance both as to the establishment of freedom from its mere presence and as to the maintenance of conditions that will prevent dense scar deposits.

In the case of a lower extremity which has suffered from some trauma and has been treated by attention merely to wound healing, the skilled masseur proceeds in a way most interesting to follow. His first three to five treatments are devoted to preliminary manipulations that are designed to stimulate the superficial structures and to accustom them to light traumatism. Rough manipulation at first may lead to the rupture of capillaries and to the heightening of irritability. Early attention is given chiefly to the skin and the subcutaneous tissues. The muscles and nerves are not so much regarded while the lymphatic vessels are given attention only as the hands pass over them in a general way.

But when serious manipulations can be tolerated as they may be after five to seven days, the deep lines of lymphatic vessels are broadly but heavily rubbed, especially strong pressure being made with the palmar surface of the thumbs.

These lymphatic vessels are felt by the manipulator as beaded cords usually running upwards from toes or fingers to the trunk, but the patient feels them as sore, tender, linear masses of denser tissue. The soreness aroused by pressure is such that a hardy person somewhat enjoys the feeling of pressure and the relief obtained by the manipulation despite the painful element. The infiltrated cellular tissue is simultaneously attacked; day by day the pressure upon both lymphatic cellular tissue and the lymphatic vessels is heightened until, if hardness and tenderness do not otherwise disappear, the masseur may apply the thumbs sufficiently heavily to make depressions in it, the tissue fluids being thus dispelled mechanically.

Here and there in the lymphatic vessels nodes of lymphoid tissue and well marked lymphatic glands are felt and, where no suppuration or pronounced disease is present, light massage upon them is beneficial. In fact after a week or two of daily treatment all these tender, infiltrated areas are made almost to disppear, with corresponding relief. My observation convinces me that the healing of broken bones under this process is more rapid than is otherwise the case and that there is much greater comfort, with speedier functional activity. The world owes Lucas-Championnière a great debt of gratitude for his insistence on massage in fractures.

Where lesions of the extremities have been somewhat neglected, after the more superficially located lymphatic apparatus has been given attention, the surgeon advises deeper manipulation, to do for the lower lying structures what has been done for those nearer the skin. It is surprising how the deep lymphatic spaces, vessels and glands come into prominence as seats of pain and tenderness after the more superficial difficulty is removed. The masseur continues his treatment actively until all tenderness and induration have disappeared.

Massage is needed for almost all wounds, surgical or otherwise, after their permanent closure is assured. The boggy, sodden or indurated tissues yield very quickly to manipulation if there has not been infection. The parts regain their normal feeling and function swiftly and the resulting scar is minimal in mass, being likely to be more pliable. Usually only a few treatments are needed.

After hernia operations and goitre resections the final result is reached much more satisfactorily and rapidly under massage.

It must be understood that the operator chosen to do the work of massaging must be adapted to the

work. Men are best for men; women for women, as a rule. And there are many unsatisfactory workers for one really useful one. It is worth while to seek out good workers, to encourage them and to give them professional support. The most satisfactory of my workers have been graduates of Stockholm and Copenhagen.

Case of Pneumonia Simulating Acute Appendicitis and Followed by Bilateral Empyema with Complete Recovery

CHARLES AUER, M.D.
New York

In the perusal of literature pertaining to pneumonia and its sequelæ, one is struck by the infrequent mention of simultaneous empyema of both sides of the chest and by the rarity with which such patients recover. It is this, together with several interesting features of a differential diagnostic aspect, which has prompted the report of such a case.

Case.—R. T., aged eight. Family history: Suspected pulmonary tuberculosis in father's sister with rectal fistula and a bone sinus of the foot also probably tuberculous. Nephritis in two grandparents. Both parents were neurotic. Albuminuria in father. Mother had had glands supposedly tuberculous removed from the neck and had a large fibroid of the uterus, at time of patient's examination.

The patient had always been rather pale and delicate and subject to colds and sore throats. She had had several socalled bilious attacks in the past, usually accompanied by fever, vomiting and pain in the abdomen.

Four days before the present attack she was closely associated with a playmate in whom there soon developed an acute general respiratory infection of the influenzal type. The patient's present trouble began with a sore throat accompanied by fever but without a chill. Two days later she complained of pain in the abdomen and vomited. She had not coughed. The chief symptom was pain in the abdomen.

The patient was a frail girl of eight years. Extremely nervous but intelligent and anxious to help make a diagnosis. Her face was flushed; circumoral pallor was present. The alæ nasi were dilating with respirations. The tongue was coated. The tonsils were large and inflamed but without spots. The heart was negative. The lungs showed slight dullness over both bases posteriorly, the percussion notes for the right and left being about the same, but with no change in breath sounds and no râles, vocal fremitus was normal. The abdomen presented a rigidity of the whole right side with tenderness over the region of the appendix. The percussion note was tympanitic. Temperature 102°, pulse 95, respiration 35. There was a trace of albumen in the urine but no pus.

An ice bag over the appendix seemed to relieve the pain and the other symptoms abated somewhat under symptomatic treatment for several days when a few moist râles developed in the base of the right lung posteriorly. The percussion note was dull but compared equally with that of the other side. After consultation with Dr. Everett Gould of St. Luke's Hospital, the chest was explored with an aspirating needle and an ounce of thick green pus obtained which, on culture, proved to be a pneumococcus infection. She now began to cough, twelve days after the onset.

The patient was transferred to St. Luke's Hospital and operated upon by Dr. H. H. M. Lyle of that institution, who resected a rib and inserted a short rubber catheter. Although considerable pus drained away in the next two weeks and, although the right pleural cavity was explored through the wound for possible pocketing and the wound irrigated with Dakin solution, the temperature remained up and dyspnea and cyanosis increased. Blood count: total, 18,000, with 86 per cent. polymorphonuclear leucocytes. In view of these findings and in spite of an x ray which, in our opinion, showed no clear evidence of pus in the other side, I explored, under considerable difficulties, the left pleural cavity and obtained several ounces of green pus, also of pneumococcic origin. Although a local anesthetic was used, the patient made a considerable ordeal of this procedure and it was not thought advisable to repeat it. The evacuation of this small amount of pus gave some relief to the dyspnea, so she was allowed to go two days longer to further fix the adhesions on the right side. Under nitrous oxide a second operation was performed, an empyema button inserted and a collapsed Politzer bag attached as quickly as possible to partly reestablish negative pressure. Care was taken by means of adhesive plaster to render, at least temporarily, this drain air tight. Stormy convalescence followed, her chief symptom during this period being a constant desire to yawn. Wolff's blow bottles were used. Examined a year later, she showed no evidence of contractures or spinal curvature, and seemed in better health than before her experience.

An examination of this history emphasizes again what so many writers have promulgated, namely, the difficulty of making a differential diagnosis between acute appendicitis and an acute respiratory infection. Here was an apparent history of previous attacks, fever, vomiting, pain, rigidity and tenderness in the right iliac fossa, all of which pointed to the appendix as the offending organ. The lack of cough and the practical absence of physical signs in the chest also tended to confuse, the slight dullness posteriorly being extremely difficult to demonstrate because it was bilateral so that the percussion note compared equally with the other side.

On the other hand there were certain facts which, in spite of the apparent presence of appendicitis,

pointed to the possibility of respiratory involvement and rendered it advisable, if the patient's condition permitted, to treat expectantly for a few days. There was a history of exposure to an acute communicable respiratory infection, the first symptoms were in the respiratory tract—a sore throat, the face was flushed, the nostril dilated with breathing and the pulse rate was low for an abdominal condition while the respiratory rate was high. Behrend states that "the occurrence of appendicitis brings up the important difference between pneumonia and appendicitis. The closest observation and the finest diagnostic acumen are required to differentiate between them. Even before the symptoms of pneumonia are absolute, the one diagnostic point that has helped me more than any other is the respiratory rate, with the playing of the alæ of the nose and the bright flush on the cheeks. The child (because we are called upon to make this differentiation mainly in children) is not able to help the physician much to arrive at a conclusion. The mechanism which causes the inability to make a definite diagnosis at times is no doubt known to all of you. The last thoracic nerves send filaments over the abdominal wall, giving rise to referred pain in the right iliac fossa. The best advice that can be given is that the appendix should be removed under gas and oxygen whenever we are in doubt. Cases could be cited to illustrate this point, but it is satisfying to know that in the cases in which pneumonia developed due to an error in diagnosis, the patients recovered." As the progress of the case under discussion shows, any operation on the appendix after the above advice would have probably proved fatal.

Behrend further states that "It happens that in my experience more cases have been diagnosed pneumonia which were really appendicitis." On the other hand, Holt says, "The error usually made is to mistake pneumonia for some other disease, rather than to mistake some other disease for pneumonia."

It will be noted that the pneumonia never did reveal itself by frank physical signs except for a few moist râles and slight dullness and yet, from the course of the disease, a pneumonia undoubtedly preceded the empyema, and was the cause of her abdominal symptoms.

Recovery in this case in spite of the wide extent of the infection and the mechanical difficulties connected with breathing with both pleural cavities open at the same time, was, in my opinion, due to two factors. These were, first, the interval of two weeks allowed between operations which induced fairly firm adhesions to bind the right lung to the chest wall before the left side of the chest was opened, and second, the nonvirulent nature of the infecting organism. According to Rose and Carless more than half of the cases of empyema in children are due to the pneumococcus. The next most common organism is the streptococcus. Eggers reports two series of cases comparing the virulence of the streptococcus and pneumococcus in which he tends to show that while the mortality in streptococcus cases may vary from 5.6 per cent. to 62 per cent., the mortality from pneumococcus cases in his cases varied from 5.8 per cent. to 17 per cent.

Ophthalmology and Stomatology*

HOMER E. SMITH, M.D., F.A.C.S.
New York

"It seems to me that the best and most hopeful feature of opthalmology is that it has relations, closer or more remote, with every branch of medicine and surgery. Indeed with almost every branch of science." This apothegm of Sir James Anderson may be supplemented by that of Sir Clifford Allbutt who said, "Diseases are not entities, nor even recurrent phases of independent events, but are partial aspects of a universal series."

With these postulates we may approach the problems of the ophthalmologist and the stomatologist with an open mind and with clarity of vision. In the first place what position does oral infection occupy in its aspect of this universal series? Is it a purely local disorder, a focus from which springs systemic infection, is it secondary to generalized or remote disturbance, or is it merely a symptom of a lowered bodily resistance? To my mind these four factors are coequal and cooperative. Does anyone believe that a pyorrhea is purely a local disease? If so, how is accounted for the gingivitis that may follow a luetic infection or be a sequel to latent gout with no joint involvement.

In the elaboration of my argument while consistency demands an adherence to my title and to specific instances of the relationship of eye to mouth diseases, yet the fact that diseases are not entities compels me to a broader concept and to a purview of the medical field. My old teacher used to say that neuralgia was a cry on the part of the body for healthy blood. It is presumably true but the cry becomes vocal when in addition there is localized irritation. I recall a case of the most violent unilateral neuralgia of the lower branches of the fifth nerve. So agonizing was this pain that the patient contemplated suicide. She had had all the paranasal sinuses exenterated with no relief. She had sound and beautiful teeth. She brought with her dental x ray films—rather lacking in definition—but sufficiently clear to rule out apical infections. Notwithstanding this I felt sure that the teeth were at fault. A röntgenogram showed three pulp stones on the affected side. Removal of these cured the neuralgia.

*Read before the American Stomatological Association.

Another source of reflex disturbance is impacted teeth causing orbital pain and neuralgia and to sensitive and decayed teeth have been attributed neuropathic keratitis.

A nice problem for decision comes up when a patient who needs operation involving the opening of the globe—iridectomy or cataract extraction—has a mouth full of rotten teeth. The time element is here the deciding factor. If it is an emergency operation leave the mouth alone. If not, extract the teeth, curette the sockets and put the mouth in the best possible condition. Then wait a week or two. In no instance must operation be done while the gums remain sore and swollen as they still harbor the infecting organisms.

It has been said that unerupted teeth are prima facie evidence of an infection in the matrix. I recall one case where an iritis promptly subsided when an unerupted canine tooth was discovered in an apparently edentulous jaw, and was operated upon.

There are those who believe that an infected root canal or an abscess at the apex of a tooth may be a primary lesion independent of the other factors I have mentioned. The following case might be considered confirmatory of this belief.

Case.—A young man working on a farm, apparently in perfect health, with no bad habits and with no history of previous illness or venereal infection, came with the statement that he could no longer see well in the right eye and that objects seemed distorted in outline. The clapboards on his house were no longer defined in straight lines but were wavy. Vision equalled only one tenth of the normal. Shortly before this he had come up before the Army examining board and this eye had normal vision. A painstaking analysis of every bodily organ and function revealed no abnormality. X ray examination of his teeth showed no apical infection but the test for vitality showed that the first bicuspid on the right upper jaw was devitalized. The ophthalmoscope of course showed no macular lesion as this particular type of disturbance of the retinal elements is microscopic and not visible to ordinary vision.

Frankly I doubted whether I had found the cause of his trouble, but nevertheless the tooth was extracted and in less than two weeks his vision returned to normal.

In every form of infection it is not the bacteria which do the mischief but the toxins which are elaborated in their life cycle and the dentine offers no more obstruction to their exit than would a coal sieve to a grain of sand.

Within the month I have had a striking demonstration of the connection between intraocular disturbance and oral sepsis. A young married woman, otherwise in good health, negative Wassermann and with negative cultures from accessible structures, presented herself with an active and progressive choroiditis. She had an artistic piece of hardware in her mouth, anchored to fixed crowns around the margins of which pus could be expressed. I advised that this denture be removed, that an autogenous vaccine be made and that she return for active immunization. I did not see her again for six months when she came again to my office. What prevented was a motor accident to her husband. She had followed my advice however and the upper jaw was now edentulous. Understand there was no other treatment whatever. To my great delight the process in the left eye had come to a complete standstill and her corrected vision was twenty thirtieths plus. In the right eye there were faint areas of depigmentation without the marginal coloration which marks a recessive process but her central vision is now twenty twentieths.

Every form of oral sepsis—pyorrhea, alveolar abscess, periapical infection, root infection and that around crowns and fillings—finds its analogue in ocular inflammations individualized in any of the ocular structures from conjunctiva to optic nerve, and more than this there may develop abscess of the orbit or thrombosis of the cavernous sinus.

Admitting for the sake of argument that all this is true, does it necessarily follow that any or all of these oral infections lead up to ocular inflammations? If so, then hardly a single individual would escape for under the artificial conditions of modern life few have perfectly sound teeth. The question of immunity, natural or acquired, now enters into the problem and here it is that the dentist needs the cooperation of the skilled clinician.

Specialism is of advantage only as it affords material for generalization and it is unfortunate that when one line of investigation be too closely followed that a loss of perspective results. The oculist is prone to dwell too intimately on local conditions and the dentist to see in the mouth only a field for exercise of his mechanical skill to conserve or replace damaged or missing teeth. Both the oculist and the dentist may overlook the fact that diseases of the eyes and mouth may not be diseases at all but be symptoms only or an end product of systemic disturbance. It is not enough to consider the teeth alone but the conditions in the buccal mucous membrane and the alveolar processes. An apical abscess does not necessarily mean infection from purely local causes nor may it be an impending menace to the bodily health; it may simply mean a lowered resistance and that the body is potentially or actually infected from other sources.

Here enters again the factor of associated infections and how these partial aspects of a universal series react to form a vicious circle. A pyorrheic involvement permits streams of pyogenic and pathogenic organisms to enter the intestinal tract and set up an intestinal toxemia which in turn reacts upon the mouth and makes futile any local treatment of diseased conditions there.

"A clean tooth never decays," is a forceful slogan for a tooth paste advertisement, but it is not true. A rachitic child might spend its entire time cleaning its teeth but that would not save the teeth from melting away unless the calcium metabolic balance were reestablished.

It is time that we get away from the rubber stamp diagnoses; diseases are not entities nor recurrent phases of independent events. We need the cooperation of the dentist and the doctor; we need the assistance of the laboratory but most of all we need the critical faculty which shall with prophetic instinct grasp the essentials of a disordered body in diseased conditions which are peculiar to itself.

111 East Thirty-ninth Street.

Syphilis of the Anus and Rectum

CHARLES J. DRUECK, M.D.
Chicago

(*Concluded from page* 205)

FACTORS INFLUENCING THE PROGNOSIS OF SYPHILIS

The diagnosis of syphilis based on the clinical aspects of the initial lesion cannot be made with absolute certainty. On the one hand, the supposed chancre might not be syphilitic and the patient therefore is subjected unnecessarily to the anguish and the hardship of a prolonged course of treatment.

Today, through our knowledge of the spirochete, with the aid of the dark field microscope, we are able in a few minutes to make a positive diagnosis of syphilis in every case of untreated chancre and to take the necessary measures to cut short the further systemic infection.

In all fluctuations of opinion as to the significance and value of the Wassermann reaction it is generally conceded that a strongly positive Wassermann reaction is found practically only in syphilis and that a strongly positive Wassermann reaction means syphilis.

Furthermore, the Wassermann reaction is used as an index of the efficacy of treatment and thus as a prognostic sign. On the theory that the Wassermann reaction is due to the presence of certain bodies in the blood that are produced as the effect of an interaction between the spirochetes and the tissues. The disappearance of the Wassermann bodies from the blood of the syphilitic, the occurrence of a negative Wassermann reaction, indicates, only the cessation of the interaction of tissues and spirochetes. It seems that a negative Wassermann reaction in a syphilitic means only that there are no foci of spirochetes in the patient sufficiently active to bring about the formation of an appreciable quantity of Wassermann bodies in the blood, but it affords no proof of the eradication of the spirochetes. We know that the late syphilitic with a gumma, in the skin, or with obvious symptoms of syphilis of the central nervous system, frequently presents a negative Wassermann reaction. We know, furthermore, that vigorous treatment in the secondary or the later stages commonly results in a negative Wassermann reaction which subsequently may become positive. As an index of the complete spirochetal disinfection of the patient, a negative Wassermann test at a given moment is relatively useless. On the contrary, however, as an index of failure to eradicate the spirochetes, a positive Wassermann reaction in the syphilitic under treatment has the greatest value and demands the continuance of treatment.

TREATMENT

In the early stage, before generalization has occurred, is the one psychological moment in the life history of syphilis when with one complete intensive course of treatment with mercury and arsphenamine we may expect a complete cure, but it must be begun immediately and pushed vigorously before the serological tests are positive.

Hoffmann asserts that a successful abortive cure of syphilis should be attained in from eighty to one hundred per cent. of all cases, provided the patient presents himself for treatment in the prepositive Wassermann period. Fabry states that it is generally admitted now that in primary lues sterilization is obtained prior to the positive Wassermann period in one hundred per cent. of all cases. Galewsky says that in all cases of early syphilis showing a positive dark field and negative Wassermann they continued to show a negative Wassermann throughout their treatment with silver salvarsan and during one year of observation following this.

TECHNIC, PRIMARY STAGE

In 1916 Pollitzer (9) outlined a method he had employed successfully and apparently without danger, of using three injections of arsphenamine, each consisting of 0.1 gm. for from twenty-five to thirty pounds body weight, on successive days, following this with eight weekly injections of two and a half grains each of mercuric salicylate. Three series in a year were employed, with a test period of two months between the series. This method was founded on the scientific theory of fractional sterilization as employed in the laboratory. The principle is alluring as it includes a concentrated attack on the microorganisms in such a manner that their development between treatments is not possible to any degree. From clinical experience it is evident that a single injection of a size compatible with safety cannot destroy all of the spirochetes present; and when the interval is prolonged between injections, the remaining microorganisms reproduce so that it is possible that almost if not quite, as many are present at the second injection as at the first, so that other factors would necessarily have to intervene before the infection is overcome. In this method it is supposed that at the first injection the major portion of the microorganisms are destroyed; and as the second injection follows so soon, many of those remaining are overcome and a few that escape this are reached with the third. That this is not literally true is evident, but the fact remains that many patients thus treated early do not show further signs of the disease. The possible dangers attending this method were discussed by many, but most observers agree that if it were safe it offered possibilities more promising than other methods.

A Wassermann blood test is recommended after each course and a spinal fluid examination after the second course. During the second year of the disease perform a Wassermann blood test every three months and lumbar puncture with a complete serological examination of the spinal fluid. If at any time the Wassermann becomes positive treatment will be renewed. If at the end of the twenty-fourth month the Wassermann blood test and spinal fluid are negative the case is considered cured.

A Wassermann examination should be made dur

ing the rest period after each course of treatments and if constantly found negative during the year two series of treatments should be given as a prophylactic measure. In the Wassermann positive cases the procedure is a continuation of that outlined for the first year.

In all patients presenting themselves with a positive Wassermann the arsphenamine injections should be six to a course and the courses of mercury should be from ten to twelve injections at weekly intervals of gray oil or mercuric salicylate. Serological tests should be made after each course until several negative results are obtained. From then serological tests should be made at two month intervals, until the test seems to become permanently negative as shown by at least five unbroken negatvie tests, each six months apart, with no treatment and no clinical evidence of syphilis before we should become in the least optimistic in regard to the case as being checked or cured.

The third year, if the Wassermann test remains negative and there have been no recurrences from the first year, a patient should pass into a period of observation with regular periods for a serological examination.

Several methods of administering arsphenamine have been developed:

1. The intravenous method may be called the universal one, because it is so universally employed. The drug enters the blood stream, and therefore this method exerts a strong appeal to those who favor direct action against the parasite invader in the blood current.

Technic.—The water is distilled the day previous to its use. The distilled water is boiled on the day of the administration of the arsphenamine. The water used is at room temperature. The arsphenamine ampoules are immersed in ninety-five per cent. alcohol; twenty c. c. of the sterilized distilled water is placed in a sixty c. c. medicine glass and the contents of the ampoule containing the arsphenamine are dropped into the glass containing the distilled water. The arsphenamine powder floats around on the surface of the water until it is completely dissolved, which takes approximately one minute. The contents of the medicine glass are now drawn up into a thirty c. c. Luer syringe. Just prior to the insertion of the needle the operator dries same with a piece of sterile gauze in order to prevent the solution from coming into contact with the tissues. After the needle is introduced into the vein enough blood is withdrawn to fill the syringe. By this means we are positive of the needle being in the lumen of the vein, and according to Kolle (10) the toxicity of arsphenamine is immediately reduced by the addition of albumin or serum. The injection of the solution is made slowly, requiring approximately one minute. The needle is withdrawn quickly and the operator raises the patient's arm and uses marked pressure at the site of the injection in order to prevent extravasation of the fluid back into the tissues.

Intrarectal is by far the simplest and least annoying to the patient, but probably not as effective as the intravenous method. In patients whose veins cannot readily be utilized for direct injection into the circulation a larger dose per rectum may be given.

The technic is simple. On the day preceding the injection the patient takes a saline cathartic and two hours preceding the injection a rectal enema is given; no food is permitted for six hours preceding treatment. Paregoric given at the time of injection helps to tighten the bowel, and the fluid then can be retained eighteen to twenty-four hours.

Technic.—The patient is placed on the table or bed in the genupectoral position and a catheter is introduced into the rectum for a distance of six inches. The method of preparation of solution is as follows:

Dissolve 0.6 gm. of arsphenamine in distilled water and add normal saline solution to make thirty c. c. Alkalinize this, making the monosodium rather than the disodium salt. This means that merely enough fifteen per cent. sodium hydroxide solution to clear the solution is employed. This is in contradistinction to the procedure in administering the drug intravenously when the disodium salt is essential.

By means of a funnel attached to the catheter or to the barrel of a Luer syringe the arsphenamine solution is allowed to pass in slowly. Upon the withdrawal of the catheter, the patient is kept in the genupectoral position as long as possible and is then allowed to assume and remain in the Sims position for a time. If the injection is given at home, the favorite time for administration is at night, so that the patient can remain in bed.

As will be noted, doses of 0.6 gram arsphenamine are recommended when the rectal route is made the channel of treatment. Some clinicians report that 0.8 gram can be safely and profitably employed, rectally.

Henry G. Marthens recommends massive doses giving as high as four gms. at an injection.

From a series of 125 cases he concluded that neoarsphenamine can be administered safely in four gm. doses; that arsenic is absorbed into the blood after these injections, and larger quantities are eliminated in the urine than after ordinary intravenous injections; that arsenic persists longer in the blood in perceptible quantities after the rectal method with large doses than after intravenous injections; finally that the rectal administration of massive doses, especially in the case of children, has a decided place in therapy, in cases in which the intravenous method cannot be used.

Mercurial administration.—Supplementing the arsenical preparations mercury should be given to our patient and the most efficient treatment is the intramuscular injection of gray oil (oleum cinereum) or the salicylate.

The insoluble salts of mercury are preferable to the soluble salts because their effect is more continuous and the injections need not be given as frequently. The injections should be given once a week deep into the gluteal muscles, although any region in which there is a thick mass of muscles may be used. The injection should be made directly and deeply into the muscles, with the strict observance of asepsis. In infantile syphilis treatment by inunction is much to be preferred to all other methods. One dram of equal parts of mercurial ointment and lanolin should be spread upon the abdominal binder daily.

TREATMENT OF TERTIARY MANIFESTATIONS

The treatment of tertiary syphilis of the anus and rectum require the systemic treatment outlined

above to which should be added full doses of potassium iodide, preferably given in milk or essence of pepsin, the dose being built up to sixty to one hundred grains daily in small frequently repeated doses.

The patient should be put to bed and the bowel relieved of all irritating material which might excite the colon or pelvic bowel. Every effort must be made to prevent septic infection. The bowels should be emptied regularly and the rectum irrigated twice daily with some bland antiseptic, followed by the injection of six ounces of one per cent. iodoform or ichthyol emulsified in olive oil, this latter to be retained. Individual ulcers may be cauterized with silver nitrate, thirty to sixty grains to the ounce and repeating the application every two or three days. The sphincters should be dilated to assist drainage.

Ulcerating gumma may be hastened toward recovery by applying daily or every other day, a piece of mercurial plaster or an ointment of calomel, one dram to the ounce. This makes a convenient, cleanly, and effective treatment.

Vascular Disturbances

LOUIS L. TEN BROECK, M. D.
Minneapolis, Minn.

(*Concluded from page* 236)

1. Nitrogen partitions as now determined offer little of value outside of an index of the renal excretory function. Chemical imbalances from split protein products lie in factors at a level higher than those now determined in blood chemistry. Studies in amino acids, especially if we go so far as to differentiate the active amino acids, promise to be of as much benefit as the determination of the fatty acids have proven in diabetes. Certain diseases suggestive of hepatic deficiency show a urine urea (blood urea normal) as low as twenty per cent. returning to high levels on a water diet and augmented by salicylates. This rise is associated with marked clinical improvements.

2. Sugar curves in relation to sugar or carbohydrate intake promise aid in determining hepatic (glycogenetic) deficiency, as noted above.

3. The significance of alkali reserve has been badly clouded by an attempt to make hydrogen ion concentration a chemical complex with an associated symptom complex. As a matter of fact, a symptom complex (such as described by Henderson—dyspneas, etc.) occurs only in extreme loss of alkalies, a loss so pronounced as to interfere with the gaseous exchange at the capillaries. Outside of this there is no direct relation between symptoms encountered and the degree of hydrogen ion concentration. The acidosis of diabetes (deficiency of isles of Langerhans, fatty acids) provokes less reactivity of bloodvessels than does the acidosis we have encountered whose origin and associated chemistry suggest hepatic deficiency (amino acids) wherein a marked vascular reaction is registered. The determining factors are not the concentration of hydrogen-ions but the character of the acid substances and adventitious products associated with perverted metabolism as well as disturbances in proportions of the blood ash. Calcium deficiencies are associated with nutritive disturbances (leg ulcerations) and disturbance of alkali proportions (in serum) provokes erratic muscular contraction (Ringer). Furthermore, chemical distortions (pancreatic diabetic and perhaps hepatic) seem to lower immunity (skin and respiratory respectively). Acidosis arises from various factors. The ultimate end of carbohydrates and fats is carbonic acid which binds the alkali only while in transport to the lungs at which point it frees them. Its precursors, carboxyl acids, carry them out through the kidneys. The ultimate end of protein acid derivatives is amidocarbamate (urea). Its procursor amino acids, likewise encroach on the alkali reserve. The most that can be claimed for alkali reserve which enters into so many complex chemical activities, is that it is a reliable barometer of distorted or arrested metabolism the nature of which requires further chemical study or interpretation by symptomatology (complexes and causative factors). These principles will explain the disappointments in forced alkali feedings which restore alkalies to high level without proportionate improvements in symptoms as comparable with a therapy that overcomes the primary cause. This can be nicely demonstrated in cases of acidosis from intestinal fermentation.

The crucial test of merit in any medical effort must eventually lie in what it offers for relief of suffering and disease. The foregoing discussion is founded on four hypotheses: a, reactivity of smooth muscle into chemical changes making the vessels a barometer of chemical imbalances; b, where chemical determinations are not definite enough in themselves to demonstrate the nature of the morbid condition (interpreted in connection with causation fac

tors and symptomatic reactions) they are still of no little value; c, a factor in intestinal fermentaion, frequent and dominating, are the anaerobes and raising the oxygen tension of the colon will result in decrease in intestinal fermentation, improvement in symptoms, and restoration of chemical balance. This is only one solution to the many complexities involved in chemical imbalances and chemical diagnosis; d, that degeneration of intestinal epithelium by fermentation (or focalized infection) is an important, if not the essential factor in determining the damage done by such fermentation (of infection) and that the restitution of such epithelial patches as above described should be the target for therapy in cases primarily due to fermentation. Abrogating these principles from consideration when confronted with such medical problems as are the basis of this work we are left where the textbooks leave us in discussing such subjects as neurasthenia. True we are admonished to look for larval hyperthyroidism or syphilis. Psychoanalysis is recommended and we are instructed to "build up patients," by which is generally interpreted forced feeding. Thus our cited cases show x ray burns in the thyroid region in spite of negative reports from indirect calorimetry. Many sufferers have their anxieties magnified by a syphilophobia without foundation. Some whose metabolic capacity is already impaired suffer further damage by forced feeding. All these errors would not be committed if a chemical report were part of these case histories. Even if such a report is not conclusive, one can remodel the mode of living along more rational lines with a chemical insight even though minute. Furthermore, a chemical determination will stay the hand of useless surgery. The choice of therapy lies in the field of casual relations. The present state of medical progress requires that we stress almost to the point on ignoring any other factor, those causes discussed under exogenous. Both for brevity's sake and because of its importance and clarity we will discuss chiefly the handling of cases whose chemical balance is thrown away through the activity of intestinal bacteria.

The intestinal flora is sensitive to dietary changes. Our present knowledge of intestinal fermentation stresses the importance of the carbohydrate factor, especially certain types, sugar, patent wheat flour and starchy tubers (potatoes). A substitution of green vegetables, whole grain, berries and especially fruits is imperative. We have seen most remarkable recovery from infant acidosis by fruit sugar (hypodermoclysis). Equally striking are the results following change to proteins (caseinates), fruit juices and appropriate vegetables. Air is also a diet for bacteria at least, and rise in oxygen tension is frequently followed by gratifying results. This rise is obtained by giving peroxides of alkalis and by enema containing Dakin chlorine compounds (see below).

Vessel muscle fibres are subject to nerve impulses and emotions. A highly trained pitcher's arm will suddenly develop transient or prolonged instability during the strain of pitching. The strain on these smooth muscle fibres during emotional storms is no less than a pitcher's arm is subject to. In fact there is unquestionably a vascular instability (some cases of socalled shell shock) resulting from violent emotions (fear). Chemical determinations should prohibit confusion with this instability on a chemical basis. Sleep is the great restorer of muscle and an unstable vascular system, either from emotions or chemical distortions, regains its stability by regular sleep as much as by any other method. Regularity in habits is indispensable.

Exercises register both beneficial and detrimental effects. When detrimental the case falls in a group of low alkali reserve. Exercise then provokes a fatigue that persists together with palpitation and mild dyspnea. This paradox is explained by the complementary relations between muscle fibre and liver cell. The former catabolizes sugar as against the liver's anabolism (glycogenesis) and thus lessens the liver's load, while muscle activity piles up the work of the liver in increasing amino acids. In the type described above, hydrotherapy and massage are desirable substitutes until conditions improve and the reserve alkali increases.

Rational medication lies in management of oxygen tension and the restitution of epithelial intestinal lining. Peroxides are given with benefit. The metal chosen depends on conditions. Due to the associated hyperperistalsis bismuth is indicated but the technical difficulties in preparing a bismuth peroxide are as yet unsurmounted. Magnesium peroxides is beneficial and seems to lack the flare back of other magnesium salts. The magnesium ion alone is valuable as a stimulant to bile flow. Its exhibition alone will sometimes effect a marked change in the chemical picture. The patchy adherence noted suggests the use of an oil with high viscosity (petroleum oils). Clinically we obtain better results when a suspension of bile is incorporated. Whether this adds to its physical properties as a lubricant or whether bile salts exert a stimulant effect on the intestinal epithelium is not known. We know that Dakin's solution vitalizes cells and it also raises oxygen tension. Dichloramine-T is miscible with liquid petroleum if first dissolved in about four times its weight of methyl salicylate concentrations up to four per cent. (two per cent. is generally strong enough) and apparently show no interreaction between chlorine and oil. They should be prepared fresh every few days. Given by Murphy drip the scope of their activity is increased. We have instances wherein the symptoms and chemical changes were totally controlled by such enemata. A combination of peroxides and such enematas seems to be effective in a large percentage of cases of intestinal fermentation.

One cannot master problems in the sick room and fail to gain a knowledge of drugs that impels their use without rational basis. Such is the case in vascular disturbances. In migraine we learned from the Rush Medical Neurological Clinic the use of bromides and from the University of Basle the use of salicylates. A Hungarian observer (reference lost) demonstrated the disappearance of indican through giving hexamethylamine. This empyrical combination affords relief at times particularly from migraine. Patients who refuse any medicament but morphine can be persuaded to take their "shot" intravenously and this combination be given without their knowledge. The substitution of feeling of well being for a morphine flare back they attribute to the mode of administration and in many instances this method has led to breaking this dependability on

morphine. These cases have afforded means for studying chemical effects of these drugs and a remarkable restitution (only temporary) in chemical balances has been found in several cases. Peruvian bark is a time honored remedy which fell into disuse when quinine was introduced. Recently it has come into its own in the form of a quinoline base, cinchonic acid. This combined with a phenolic base makes what promises to be a better substitute for salicylates. We should not frown too much on drugs. We have been giving kalium iodide for centuries as a drug. Now we find it an indispensable factor in sustaining health condition and we are now making it an essential part of our drinking water. At least in this field of chemical diagnosis we are doubly fortified in our choice of drugs; both symptomatology and therapy are susceptible to control by chemistry.

SUMMARY

Our prime object is not to describe a disease entity nor even a symptom complex. We are confronted by the problem of staving off deteriorations in stamina and in coping with this problem we have observed certain phenomena and the therapy that these phenomena have suggested has proven beneficial. Our position is comparable to that of a woodsman whose woodcraft gives him certain signs (as the northerly location of tree moss) by which he directs himself without deviation to his objective. We believe that further studies will add to such signs and bring the clinician to his objective with increasing directness.

What we present here are: a, certain clinical findings will come to us either in the presenting symptom or those deduced in the history and examination which will be indicative of vascular disturbance; b, once determined a causative factor should be determined in which we stress activity of intestinal flora; c, the reactivity of bloodvessels in primafacie evidence of chemical imbalance and a careful chemical analysis should follow, which must be interpreted in the light of symptoms present and causative factors; d, this will lead to a more rational therapy the results of which should be attended with further chemical analysis to establish a further parallelism between the clinical and chemical.

CASE HISTORIES

Unfortunately many histories of value are not available. King has recorded similar observations on rabbits.

CASE I.—(A. J.) Presenting symptoms, malaise, asthenia, insomnia, nervousness. Previous history: A stay at a State hospital following a nervous breakdown. At high school the physical examination was negative except for tenderness along the liver border. Treatment: Restricted starches, medication, cinchonic acid derivatives and salines. Blood chemistry: Alkali reserve 40, ten days later 58.

CASE II.—(R. L.) Complaint: Seen in hysterical attack brought on by overwork. There had been an obstinate constipation and the diet was excessively starchy in nature. The physical examination was negative except for flatulency. Sedatives, cinchonic acid, chlorine oil enemata were given. Alkali reserve after abatement of nervous symptoms 47, after five days enemata 58.

CASE III.—(M. M. J.) Asthenia, unsteadiness developing into auto driving, flatulency. The patient had been advised an operation on the gallbladder. Heavy white bread, cake and potato eater. Examination showed flatulency, liver border tender, but not localized. Salines with chlorine enemata were given, fruit and green vegetable diet emphasized the blood chemistry; alkali reserve 45, nine days later 56. Improved.

CASE IV.—(M. McL.) Complaint, periodical headache, chronic constipation, nervousness, inaccuracy in work. The physical examination was excellent. A good boxer. The treatment consisted of oil enemata (chlorinated). Blood chemistry, alkali reserve 50, no headaches during treatment. One week later much improved, alkali reserve 60. Sugar (seven hour fast) 75, creatinin 1.5. Seen again during attack of headache, alkali reserve 38 (very nervous). Two days later 55. Treatment, magnesium peroxide and chlorine enemata.

CASE V.—(M. M.) Complaint, malaise, easily fatigued on exertion. Dysuria nervous attacks. History showed an attack of influenza leaving patient with alternate diarrhea and constipation with acrid stools. Treatment, restricted starches, chlorine enemata, mercurochrome for pyelitis (intravenously). Blood chemistry, alkali reserve 50, ten days later 68. Diarrheal attacks ceased. This patient probably has an endocrine imbalance.

COMMENT

1. All pathological changes are not limited to the median coat, but sudden changes which involve it are the first and foremost to manifest themselves clinically. So in other fields (etiology, pathogenesis) such phenomena as are the soonest and most clearly registered in clinical procedure are those that are stressed. We aim to use these phenomena as stepping stones to further clinical success.

2. Heightened chemical activity is a phenomenon not limited to the hormones but is registered with less complex organic products and with simple inorganic ions (Ringer's alkalies).

3. One can not progress far in the study of chemical imbalances without running into conditions which register endocrine deficiency. Nor will material progress be made in medical chemistry until the medical aspect of these endocrine hormones is understood. One endocrine function (ovarian) because of its cyclic nature (menstrual cycle, pregnancy cycle, etc.) lend itself to ready detection. We cite certain case histories which show its relation to chemical imbalances and vascular disturbances. We avoid a discussion until the simpler phases of this problem are better understood.

4. No greater blow could be struck this most promising science than to destroy the interdependability between it and clinical findings. The laboratory is as yet no place to make an isolated chemical diagnosis.

5. Reference is here made to the studies of Cannon, Carlson and others on the dynamic (muscle) phenomena observes in the alimentary musculature and their relations to the alimentary sensations of appetite, hunger and pain. These five smooth muscle systems afford a wealth of knowledge and a most promising field for study in muscle dynamics when

the muscle phenomena of each system are correlated and compared. Thus each has its tonal status, each is the seat of colics (known by different name) and each has its asthematic attacks. Mucous colitis is so accredited and we are meeting with distortions of urethral contractions asthmatic in character associated with chemical imbalances and frequently concurrent with mucous colitis. In some cases this combination of attacks seems to be increased under pituitrin. We had some time ago a case of asthma (following thyroidectomy for pressure dyspnea) concurrent with a period of amenorrhea. The bronchial tubes were hypersusceptible to dampness which provoked asthmatic seizures. This hypersensibility receded with the return of menses (restoration of endocrine balance). Unfortunately we did not appreciate the value of chemical studies at that time. So much of what we call symptoms are concerned with involvement of muscle dynamics, so much of therapy undertakes the rectification of the same that it is surprising that so little is said and known of muscle behavior. In passing it may be of service to note how promptly some of the cases of combined colitis and dysuria are relieved by hot retained alkali enemata.

6. Advanced cases suffer from attacks resembling angina. The conditions requisite for an electrocardiogram mitigate against the occurrence of vasomotor spasms. We have been unable to obtain a record of the heart during an attack.

7. Superimposed psychoses are an admitted sequela of prolonged and severe migraine.

8. It is our purpose to publish a description of apparatus and methods that will much simplify the cost and effort in gas analysis.

9. Determinations in amino acids have so far brought no conclusions from bedside observations. Unfortunately our observations on liver infected rabbits were destroyed. It is probably in this or similar fields that a chemical differentiation between pancreatic and hepatic deficiency will be established.

10. The shortcomings of alkalization in diabetes at least is disclosed by insulin. The former will alter alkali levels without commensurate clinical improvement as is the case with insulin. Furthermore, the neutralization of the chyle destroys that cycle which stimulates pancreas and liver through a duodenal hormone activated by acid chyle. Thus alkalization disturbs the hormopoietic balance when given by mouth but by rectum results will sometimes follow when disappointment follows oral administration (mucous colitis). The complexities of the study of acidosis are disclosed by the variety of agencies that influence a low alkali reserve, some of which are here enumerated: a. Rest and light outdoor recreation. Severe exercise heightens acidosis. b. Diet, green vegetables, fruits, caseinates, as compared with potato and patent wheat flour starches and sugars. It is surprising the number of cases of diminished reserve which give a long history of such an unbalanced diet. c. Relief of pent up excretions (infected), such as infected urine retained above a ureteral kink. d. Raising oxygen tension of bowel, by enemata containing chlorine, by oxygen liberated from metallic peroxides (magnesium). c. By endocrine hormones, insulin, diabetes, ovarian residue also agomensis (ciba) in premenstrual acidosis, ovarian residue in climacteric hypertension with acidosis, corpus luteum in pregnancy. f. Drugs: Quinolium derivatives—chinoidin (crude), cinchonic acid, derivatives as phenyl cinchonic acid, phenolic acid derivatives as salicylates, and magnesium ion.

Another relationship disclosed in our studies is the frequency with which such states as the pathologist describes as lowered immunity (wherein members of the normal skin or mucous membrane flora become pathological), are concurrent with a diminution of alkali reserve. A subsidence of the infection has been found to parallel a rise in alkali reserve.

11. From observations on tissue reaction surrounding the infected zone to the application of Dakin's solution (war surgery).

12. The recommended solvent, chloroform, stimulates peristalsis excessively though not as a rule painfully. In this respect we have found it superior to a Noble's enema. Vegetable oils are solvents; where mineral oils are not so we use vegetable oils. Nearly all react with the alkaline hypochlorites and some with dichloramine-T. Methyl salicylate, however, is suitable, at least if freshly prepared.

13. The discussion of these drugs is advanced to throw light on the subject of vascular disturbances and their symptomatological expressions and not to advance their use in therapy which, however, will prove to be now and then serviceable.

14. By salines are meant the three salts, bromides, salicylates and hexamethylamine described.

15. The frequency with which these cases of atrophic colitis (spastic) have a history of an unbalanced starch diet is noteworthy.

16. By negative we mean that the ordinary physical examination fails to disclose any condition that can be ascribed as a causative factor of the presenting symptom.

17. So many cases of pronounced nervousness we find with chemical imbalances a word of comment is not amiss. In the first place these cases are at the lower margins of alkali reserve from 40 to 35 as a rule. If we do not get some such a reading we are convinced that our work is technically incorrect or that there is another factor causing nervousness, besides chemical imbalance. Another feature is lack of refreshing sleep. We have seen patients sleep with short periods of wakefulness for eighteen hours and still complain of no alleviation of fatigue. Frequently, patients will complain they do not sleep when every test shows them sleeping long and soundly. There is no rest in sleep with an acidosis of severity (always meaning by acidosis that concurrent metabolic disorder which is the basis). Even somnifacients do not yield refreshing sleep. The influence of sleep producing drugs on alkali reserve we found as follows:

Patients under treatment who report themselves refreshed by sleep we know show an improved blood chemistry picture. In fact we are ready to advance the dictum that repose is possible only under a correct chemical balance. If this proves true it opens up an immense field for study and improvement in the use and manufacture of somnifacients, and will prove a boon to the sleepless.

My thanks are due the Presbyterian Hospital (Chicago), and its staff, particularly Dr. Thor Rothstein, for assistance in these studies.

Three Cases of Mastoiditis with Interesting Complications*

By JOSEPH FRIEDMAN, M.D.
and SAMUEL D. GREENFIELD, M.D.
Brooklyn, N. Y.

ACUTE MASTOIDITIS WITH THROMBOSIS OF LATERAL SINUS.

We present below the report of a case of acute mastoiditis, with thrombosis of the lateral sinus, discovered at primary opening of the mastoid, in which operation was followed by recovery. Thrombosis of the lateral sinus is usually a postoperative complication. Only in rare instances does the operator come upon a thrombosed and necrotic sinus at the primary mastoid operation that has not been diagnosed or suspected. In 1920 (1) we reported such a case, in which upon opening the mastoid cells we found a large perisinus abscess, the sinus bathed in pus, the sinus wall black and necrotic, and free pus in the lateral sinus. In this case the involvement of the lateral sinus occurred as a complication of an acute mastoiditis and was not diagnosed before operation. In the case we are now reporting the sinus complication was engrafted upon a chronic mastoiditis during an acute exacerbation. The diagnosis in this instance, however, was made before operation.

CASE I.—S. R., aged thirteen, male, was admitted to the Beth Moses Hospital, on May 21, 1922, complaining of pain in the right ear, discharge from both ears, headache, abdominal pain, and constipation. His family history was negative. The patient had had discharging ears since childhood, but otherwise had enjoyed comparatively good health. The present illness dated back to May 16, 1922, five days prior to admission to the hospital, at which time he began to complain of severe pain in the right ear. The discharge which had always been scanty now suddenly became copious. Examination at this period showed a foul scanty discharge in the external canal of the right ear with a drum membrane presenting a large attic perforation. The hearing was diminished about one third normal. There was no mastoid tenderness, and no evidences of any acute process going on in this ear. In the left ear there was a profuse discharge in the canal, the drum membrane presented a large central perforation, and was markedly inflamed and thickened. Hearing was markedly diminished. There was only slight tenderness over the mastoid region. Temperature was 102°, pulse 98, respirations 24. With these findings we decided to observe the patient for a few days.

On May 18, 1922, the patient's temperature rose to 104°, and he complained of severe pain in the left ear; also pain in the right side upon deep respiration. He had a hacking cough, and a general physical examination showed moist râles over the right base. On May 19, 1922, he had a distinct chill. This was followed by a rise in temperature to 104°, which remained practically constant. The mastoid was slightly tender. Palpation over the emissary region was slightly painful and there was no edema. After due deliberation we decided there was an otitic complication or a pulmonic condition which had not yet become fully manifest, and we advised that the patient be taken to the hospital for observation.

On admission, physical examination revealed the following: A boy, aged thirteen, anemic and pale, appearing to be acutely ill. Pupils were regular, reacting to light and accommodation. Ears showed slight mastoid tenderness over the left tip. His tongue was coated, and teeth in poor condition. The neck showed no adenopathy, no rigidity. Heart was normal, lungs showed diminished breathing over right base posteriorly with occasional fine dry râles. There was dullness on percussion over the same region. The abdomen was somewhat tender over entire surface, but no rigidity. Liver and spleen were not palpable. Reflexes of extremities were normal.

Diagnosis by admitting physician was acute mastoiditis, left, and lobar pneumonia, right lower. Blood culture was taken by Dr. Bender. On May 22, 1922, urine examination showed slight traces of albumin but otherwise was negative. White blood cells, 15,000; polymorphonuclears, seventy-seven per cent. Lumbar puncture (Dr. Zobel) fifty c. c. of clear fluid withdrawn under increased pressure, subsequent report otherwise negative. Blood culture reported sterile after twenty-four hours. The patient's condition was practically unchanged. Cough was loose and productive, but not troublesome.

On May 23, 1922, an x ray of the mastoids was taken by Dr. Bernstein. Mastoid cells on left side showed loss of detail with almost complete loss of structure. The condition was probably that of a moderate early involvement of the left mastoid. Blood culture was reported sterile after forty-eight hours. Another specimen was taken. Widal reaction with dilutions 1:20, 1:40, and 1:80 was negative after one hour.

From May 24 to May 30, 1922, the patient was kept under observation. The temperature curve was not typical of sinus thrombosis, the complication under consideration. The lung condition, although not very definite, seemed to clear up but the temperature did not abate. The latter was not very remittent and there was absence of chills, but profuse sweats were frequent. Under these circumstances we could not bring ourselves to operate. Repeated blood cultures were negative until June 1, 1922, when the laboratory reported streptococcus hemolyticus fifty colonies to the c. c.; with this finding we advised immediate operation.

On June 1, 1922, operation was performed. The mastoid was small and sclerotic. There were diseased granulations and free pus present about the region of the antrum. We cleaned out the mastoid

*Taken from the otological service of the Beth Moses Hospital, Brooklyn, N. Y.

thoroughly and found the sinus plate necrotic. Removal of the latter disclosed the lateral sinus covered with diseased granulations; the sinus wall was much thickened and discolored. We packed the mastoid cavity and went into the neck. The jugular was ligated below the facial and the wound drained. Returning to the sinus, the latter was packed off and incised and about a dram and a half of free pus evacuated. Examination of the specimen was subsequently reported streptococcus hemolyticus. There was no bleeding from the torcular end upon removal of the plug. We uncovered the sinus plate further back and then upon curetting out a number of well organized clots we finally obtained bleeding, but not of a very free nature. Removal of the bulbar plug was not followed by bleeding. Even after clots were removed no bleeding occurred. By this time the patient was pretty low and we quickly packed the mastoid wound. The patient was given an intravenous injection on the table and put upon stimulation.

On June 3, 1922, the patient had rallied from the operation, his pulse was much better, but the temperature had again risen to 103°. A blood culture was taken; blood count, white cells, 16,000; polymorphonuclears, seventy-eight per cent. June 4th, 5th, 6th, 7th and 8th, the patient's condition seemed to improve. The high temperature persisted, however, with remissions, the crest of each elevation being lower with each subsequent rise. Blood cultures were taken daily. On June 4th, there were twenty colonies; on June 6th, there were four colonies, and on June 7th and 8th the reports were sterile after twenty-four hours. Dressing was changed on June 8th; nothing unusual noted. On June 9th, the temperature reached normal for the first time, and thereafter it never rose above 100°. The patient improved rapidly, gaining in strength; his appetite was good, and he slept well at night. On June 21st, the patient left the hospital well on the way to recovery.

Dressings were continued in our offices until July 27, 1922, almost two months after operation, at which time he was discharged as cured. The middle ear was dry, but there was present the same central perforation noted at the time of the first examination. The hearing was markedly diminished, due purely to a conductive lesion, the bone conduction showing an increased Schwabach. The neck wound and the posterior wound were both securely and firmly healed.

SINUS THROMBOSIS WITH SPONTANEOUS RECOVERY

The following case of acute mastoiditis presented symptoms typical of sinus thrombosis, which persisted for one week. Recovery took place without operation.

Otologists agree that in a given case in which after a mastoid operation there appear symptoms of sepsis that cannot be accounted for elsewhere, we are justified in making a diagnosis of sinus phlebitis or thrombosis. A positive blood culture makes the diagnosis absolute. There are cases, however, in which this latter corroborative finding is lacking and under these circumstances conservatism must be observed for a longer period. If at the time of operation the sinus wall is found to be diseased our suspicions are more or less confirmed even without a positive blood culture. Nevertheless, the case we are reporting is one in which symptoms of sepsis followed the mastoid operation. The patient's condition, instead of growing progressively worse, remained fairly good. There was absence of pallor, and the blood cultures were returned negative. It was for this reason that we procrastinated in operating upon this patient even in the face of six distinct rises of temperature, and that our conservatism was justified is evidenced by the patient's recovery without operative intervention.

Case II.—I. A., male, aged fourteen, was admitted to Beth Moses Hospital on April 10, 1922, complaining of discharge from the left ear, pain, and headaches. His family history was negative, and his previous personal history showed that he had had the usual diseases of childhood. He had always been anemic and undernourished, but never had ear trouble previously. His present illness dated back five weeks prior to admission to the hospital, at which time he suffered from earache. The ear was irrigated and several days later the drum membrane ruptured spontaneously. The ear discharged profusely for several weeks and then gradually subsided. The pain in the ear persisted. One week prior to admission it increased in severity to such an extent that the patient could not sleep at night. Headaches were persistent over the left parietal region.

Physical examination upon admission showed a boy, aged fourteen, who appeared acutely ill. Pupils were regular, and reacted to light and accommodation. His teeth were poorly kept, tongue coated, breath foul. The right ear was negative, left showed marked edema over the mastoid region. There was tenderness over antrum and tip, and emissary region; discharge was moderate in amount. The drum membrane presented perforation in anterior quadrant, with marked sagging of the posterior superior canal wall. Neck, chest, abdomen, extremities, all were negative.

Diagnosis, acute mastoiditis, left. X ray report by Dr. Bernstein: Left mastoid showed breaking down of cell outlines; white blood cells, 12,000; polymorphonuclears, seventy-six per cent. Urine examination showed slight traces of albumin, otherwise negative.

A simple mastoid operation was performed on April 11, 1922. The left mastoid was opened and found to be extensively diseased, free pus was encountered far back to the sinus plate, the latter being softened, and the sinus covered with granulations over an area one fourth of an inch in diameter. The mastoid was thoroughly cleaned out and the tip removed. The cavity was packed with iodoform gauze. On April 12, 1922, the patient had rallied from the operation and was fairly comfortable; temperature 101°, pulse 90, respiration 22. On the 13th, 14th and 15th, the patient improved rapidly, and it appeared that he was going to have an uneventful convalescence. His appetite was good, and he slept well at night. On the 16th the first dressing was changed. The wound was found to be clean, and the cavity was repacked lightly with plain gauze. On the evening of April

19th the patient's temperature rose to 102°, and he complained of headache. The dressing was changed the same day, wound was found to be clean and nothing unusual noted.

April 20th, the patient had a chill, followed by a rise in temperature to 104°, after which there was profuse sweating. Blood culture taken by Dr. Bender. Spinal puncture, twenty c. c. of fluid withdrawn under slight pressure; pathological examination of fluid negative. Urine examination was negative. White blood cells 13,000, polymorphonuclears seventy-one per cent. On April 21st blood culture was reported sterile after twenty-four hours. Another specimen was taken. Patient's temperature that evening rose again to 103°, but there was neither chill preceding nor sweat following. The placing this on record as a case of sinus phlebitis or thrombosis in which recovery took place spontaneously. Nothing but an involvement of some portion of the blood stream after a mastoid operation can we conceive as giving rise to such a clinical picture and running such a clinical course. The wound was clean, ruling out septic absorption from this site. There were no evidences of inflammation of any kind of the wound edges, or the region thereabout, thus ruling out erysipelas. The heart and lungs were normal throughout, and the urine was negative. We are therefore assured that the source of these six distinct elevations in temperature, with such sharp remissions, should be sought for only in the lateral sinus.

At the primary operation the sinus wall showed

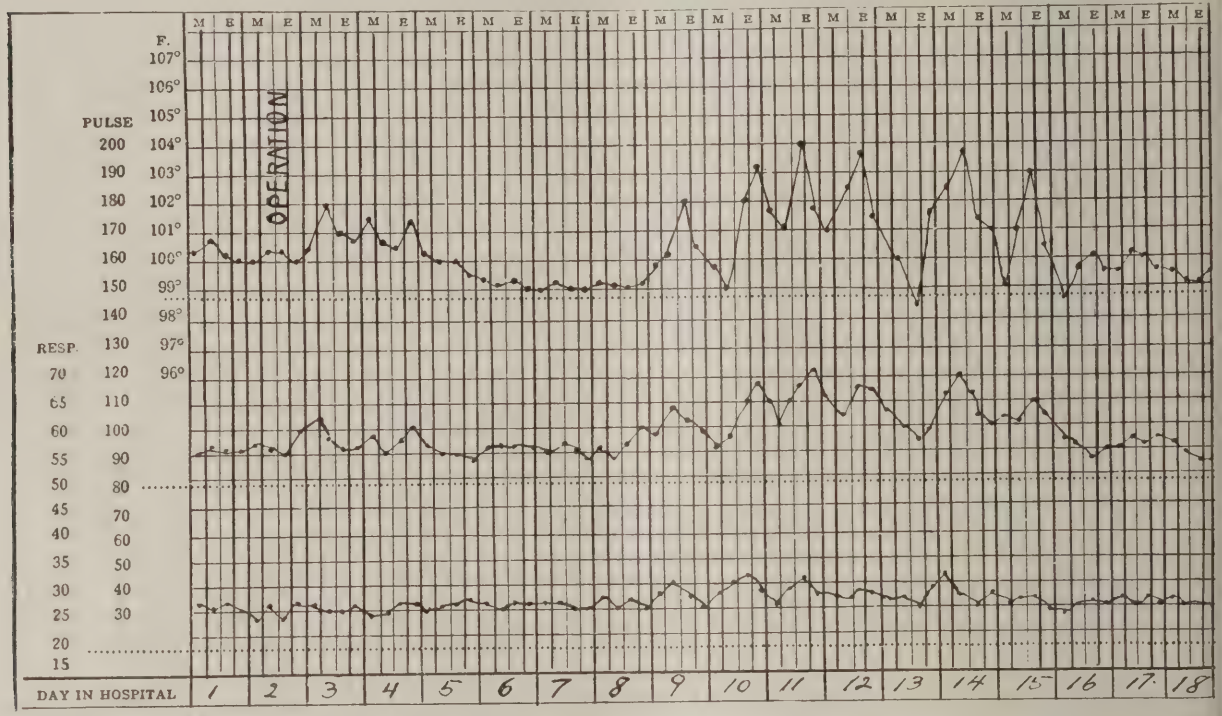

Chart.—Showing the clinical course of a case of mastoiditis simulating sinus thrombosis. (Case II.)

general condition of the patient, however, was fair and he did not seem to be acutely ill. Dressing was changed. The wound was clean, no evidences of cellulitis. Pressure over posterior of wound seemed to elicit pain. On each of the following three days the patient had a distinct rise in temperature above 103°. In the morning the temperature remitted. There were no chills but sweating occurred; yet the patient seemed comfortable. Repeated blood cultures were negative. The highest blood count during these three days was white blood cells, 15,000; polymorphonuclears, seventy-eight per cent. On April 25th, for the first time in six days, the temperature did not rise, and for some reason it remained below 100° thereafter, and although we did not resort to any operative procedure, the patient went on and made an uneventful recovery. On May 1st he left the hospital and on June 3d, almost eight weeks after operation, we discharged him as cured. The posterior wound was firmly healed and the middle ear was dry.

After due deliberation we almost feel justified in evidences of disease, and it is reasonable to suppose that the septic nature of the temperature should be attributed to extension into the sinus. This possibly was an infection, not so severe as to cause involvement of the general blood stream, being limited to that particular portion of the sinus. We are certain that in the hands of some more radical practitioners this patient would surely have reached the operating table even before the sixth rise in temperature, but in the absence of confirmatory blood cultures, and with the patient's general condition not seemingly growing, we felt justified in waiting. As a matter of fact, the patient was scheduled for operation on the seventh day, but the temperature failing to rise, we decided to wait still longer, luckily for the patient.

CHRONIC MASTOIDITIS. ACUTE EXACERBATION. RADICAL MASTOID OPERATION FOLLOWED BY ACUTE ENDOCARDITIS AND BACTERIEMIA.

Case III.—G. L., aged thirteen, female, was admitted to the Beth Moses Hospital on June 29, 192

the chief complaint being pain in the left ear, swelling over the mastoid and discharge. Her family history was negative. Her previous personal history showed that seven years ago, at the age of seven, she had a severe attack of acute articular rheumatism, at which time the heart became involved. As a result, she was left with a chronic valvular lesion, but she experienced no inconvenience, no shortness of breath upon exertion, and apparently enjoyed good health. Two years ago she had an attack of acute otitis media. The ear ruptured spontaneously and discharged profusely for several months, after which time it abated for the most part. Ever since the ear had been discharging more or less freely, the discharge having a distinctly offensive odor.

The patient's present illness began four weeks prior to admission to the hospital, when she took cold and several days later began to complain of severe pain in the left ear. The discharge increased in amount and headaches were noted, particularly in the evening. The condition continued and apparently grew progressively worse. One week later there appeared a swelling behind the left ear and soon after the headaches seemed to be somewhat mitigated. The family physician treated this swelling expectantly for two weeks. It gradually increased in size until one day before admission to the hospital when we saw the patient in our office. At this time the following was noted: The patient was markedly anemic and pale, and looked acutely ill. Her temperature was 102°, respiration 27. Examination disclosed a profusely discharging ear, sagging and narrowing of the canal, with a fluctuating swelling behind the auricle. A diagnosis of acute mastoiditis was made, and the patient advised to enter the hospital for immediate operation.

The important features of the physical examination at time of admission on June 29, 1922, at 6 p. m., were:

The otological examination was as noted above. The heart examination revealed a rather vigorous apex beat located within the mammary line, in the fifth intercostal space. Palpation disclosed a distinct thrill over the mitral area. Percussion showed some cardiac enlargement outward and downward. Upon auscultation there was noted a presytolic murmur with an accentuated P^2, also a systolic blow transmitted to the axilla. The muscular quality of the heart sounds was otherwise good. The remainder of the physical examination was negative.

On June 30, 1922, the white blood count was 28,000, polymorphonuclears eighty-five per cent. Urine was negative. X ray report by Dr. Bernstein was as follows: Left mastoid showed complete obliteration of cell outline; mastoid area seemed rather dense with scattered areas of pus formation. Sinus could not be visualized. Condition seemed to be an acute mastoiditis engrafted upon a chronic sclerotic mastoid. Radical mastoid operation was performed on June 30, 1922.

A large quantity of pus was found beneath the soft parts. Retraction of the periosteum revealed a large cortical perforation in the region of the antrum. The mastoid was extensively diseased, and was thoroughly cleaned out, after which we proceeded to the classical radical operation. Siebenmann's plastic was used; the posterior wound sutured one third, and the cavity cleaned and then packed with iodoform gauze. On July 1st the patient had rallied from the operation; temperature 100°, pulse 110, respiration 28. On July 2d the patient improved rapidly. The temperature reached normal on the fifth day and never rose above that. The pulse was good, and there were no evidences of any cardiac involvement. The dressing was changed on the fifth day, the wound was clean, and nothing unusual noted. In view of the fact that it seemed this patient was going to have an uneventful recovery with the temperature flat for five days, she was discharged from the hospital on July 10, 1922, eleven days after operation.

The patient came to our office for subsequent dressings on July 13 and 15, 1922. She appeared well and complained of no pain, slept well at night, and had a fairly good appetite. On July 16th we were called to see her at her home at which time she had a temperature of 103°, pulse 110, respiration 32. She did not give a history of having chills, did not vomit, was not dizzy, but nevertheless we suggested return to the hospital. She was readmitted on July 17th.

On July 18th the temperature remitted in the morning but reached 103° in the evening, pulse 145, respiration 38. Blood culture reported negative for twenty-four hours. White blood count, 12,000; polymorphonuclears, eighty-six per cent. Heart examination showed the pulse to be rapid, weak and markedly irregular as to volume and rhythm; visible pulsations in neck marked; cardiac apex one inch beyond nipple line in sixth intercostal space; marked thrill over precordium. Heart enlarged downward and outward beyond anterior axillary line; heart sounds weak; first sound poor, muscular quality; presystolic roll audible. P_2 still audible, loud blowing systolic murmur present transmitted to the axilla and back.

On July 19th the temperature was 102°, pulse 160, respiration 44. Patient was dyspneic and slightly cyanosed. Lung examination was negative. Blood culture reported sterile after hours and another specimen taken. Cardiac condition had not improved.

On July 20th the temperature was 103°, pulse 158, respiration 45. Blood culture reported the presence of Streptococcus viridans; incubation period forty-eight hours; 100 colonies to the c. c. of blood. Mastoid wound was dressed. The wound was found to be clean, with but little attempt at granulation. White blood cells, 13,000; polymorphonuclears, seventy-eight per cent.; red blood cells, 3,200,000; hemoglobin, sixty per cent. With the presence of a positive blood culture of the Streptococcus viridans and with evidences of an acute endocarditis it was decided that the case was no longer otological and the patient was transferred to the medical service.

Practical Therapeutics

TWENTY-SEVEN CASES OF SYPHILIS TREATED BY INTRAVENOUS INJECTIONS OF METALLIC MERCURY*

E. Almore Gauvain, M.D.
and Arthur M. Persky, M.D.
Brooklyn, N. Y.

The intravenous use of mercury, either as salts or metallic mercury, is obviously of growing importance in the treatment of syphilis. Yet, in spite of this, the literature and textbooks on pharmacology are incomplete, which fact may be due to a lack of sufficient clinical experience. The number of mercury preparations which have been used intravenously is unusually large, the majority of which have received more or less satisfactory comment. Yet, in few instances, has any mercurial been given a fair trial, especially by competent medical authorities, except in Germany where they have been used quite extensively, and reported favorably.

In going over the reports, we find that the main disadvantages are, first, a tendency to thrombophlebitis, and, second, when used in larger doses, the production of stomatitis and nephritis. On the other hand, where no such unfavorable results were found, there was no distinct advantage of the intravenous over the intramuscular route.

Mercury intravenously compares favorably with arsenic in causing the disappearance of cutaneous lesions, and acts not merely as a symptomatic remedy, but exerts a definite action on the course of syphilis. Howard (1) reports favorable cutaneous and serological results by the use of mercury cyanide intravenously. In over five thousand injections he has not observed any untoward reactions. On account of the pain caused by intramuscular injections, Butler (2) has used a synthetic preparation, mercurosal, intravenously, which has not produced symptoms of mercurialism, nor any unpleasant reactions in his hands. Therapeutically, this preparation was considered just as effective as any other mercurial by Williams (3).

On the other hand, Cole, Driver and Hutton (4), report the use of mercurosal in thirty-eight patients with syphilis who were under close observation. Many of these patients improved under its use, but no definite evidence was obtained indicating the superiority of this preparation over other mercurials.

White (5) and his associates, in ninety-six cases, have used flumerin, a mercurial drug suitable for intravenous injections, with low toxicity and absence of local irritating qualities. Their results have definitely shown that flumerin is of value in the treatment of syphilis, although it should in no way supplant the arsenicals.

Brumauer (6) has used a colloidal preparation of mercury, diphasol, containing five per cent. of metallic mercury. Reactions were few and slight, and the usual signs of mercurial poisoning rarely noted. As a rule, primary and secondary lesions cleared after five or six injections.

Ireland (7) reports the treatment of fifty patients with mercodel (then called lueside) being enabled to give much larger quantities of mercury without any disagreeable reaction of either a general or local nature. He further remarks, in the same article, that he believes the ability to administer larger quantities of mercury than has hitherto been possible will markedly advance the treatment of syphilis.

Believing also, this last statement to be true we have treated and are here reporting, twenty-seven cases of syphilis, in various stages, from the service of Dr. Alfred Potter at the Kings County Hospital, with intravenous injections of a colloidal mercury, known as mercodel.

Mercodel is provided in ampoules of five hundred milligrams of metallic mercury in a very finely divided, or colloidal, state, and 2.43 grams of glucose. The contents of the ampoule are to be dissolved in fifty cubic centimetres of sterile distilled water, the glucose making an isotonic solution of the whole. Since the mercury particles settle rather rapidly, it is necessary to shake the solution thoroughly for a few seconds before the injection, to insure having the proper quantity of mercury in each cubic centimetre of fluid withdrawn from the container.

The technic of the administration is as follows: The solution having been made as above, a glass adapter filter containing cotton is placed on the syringe. Venipuncture is then made in the ordinary manner, after which the mercodel solution, after shaking, is drawn through the cotton filter into the syringe, the filter is then removed and the syringe attached to the needle, which is already in the vein and the solution rapidly injected (one half minute). Slow injection of the solution allows a considerable quantity of the metallic mercury to adhere to the sides of the syringe, with a consequent loss in the quantity received by the patient. This is also the reason for placing the needle in the vein before drawing the solution into the syringe.

The injection does not really consist of a solution of mercury, but a temporary suspension of the mercury particles, which is of a grayish color. At first one would fear that embolism would occur, but upon reflection one realizes that metallic mercury is a true liquid, and can therefore pass through even the finest of capillaries.

The part played by mercury in the treatment of syphilis has long been known, and the ground it has given way since the introduction of the arsphenamines is gradually being recovered.

That this metallic mercury is soluble in fats, oils and lipoids, has been proved, and its effectiveness is held to be due to this fact.

In order to show the rapidity with which this mercury penetrates the various organs of the body the manufacturers injected sixty milligrams into a rat, which was killed and exsanguinated two hours later. Analysis of the organs showed forty per cent. in the liver, thirteen per cent. in the spleen, and five per cent. in each the blood, heart, brain, kidneys, and lungs. There was six per cent. in the stomach and

*Read before the Brooklyn Urological Society, Tuesday December 9, 1924.

intestines with contents, and the remainder, eleven per cent., was in the muscle, bone marrow, etc.

Of the twenty-seven cases we are about to consider, six were in the primary stage, in five both primary and secondary lesions were present, seven were secondary alone, seven tertiary, and two were of congenital syphilis. The youngest patient treated was fourteen years of age, and the oldest was forty-six.

Four cases received only one injection; six cases, two injections; one case, three injections; two cases, four injections; two cases, six injections; five cases, seven injections; one case, eight injections; one case, nine injections; one, ten injections; one, eleven injections, and one, twenty-five injections.

In addition to these there were two cases, one with a primary lesion which healed after two injections (260 mgm.), when the patient left the hospital, returning three months later with mucous patches, for which he received five more injections (640 mgm.). In the other case the patient had a primary lesion with a generalized maculopapular secondary lesion for which he received ten injections (1.91 gms.) and returned three months later with a papulovesicular secondary lesion, when he received nine more injections (0.9 gms.).

In twenty-four cases the Wassermann was four plus at the beginning of treatment, in two cases it was three plus, and in one case of tertiary syphilis with gumma of the palate, it was doubtful. The first case of recurrence, in which only two injections had been given, the Wassermann was four plus on return, and the other, having had ten injections, it was three plus on return.

Of the twenty-seven cases, Wassermann tests were not obtained later in treatment in twelve cases—these being divided as follows: one injection, four cases; two injections, five cases; four injections, one case; six injections, one case. Also in the first mentioned case of recurrence, no discharge Wassermann was taken on either visit.

Of the remaining fifteen cases the following results were obtained: Seven were improved serologically, and eight were unimproved serologically. Of the cases improved three were three plus after seven injections or 1.03 gm., nine or 0.85 gm., and eleven or 1.33 gm.; two were two plus after seven injections or 2.45 gm., and ten or 1.44 gm.; one was doubtful after nineteen injections or 2.98 gms.; one was negative after eight injections or 1.01 gm. plus eight salvarsan injections.

The effect on the lesions was more encouraging even than this. Excluding the four patients who left the hospital after only one injection, and in which sufficient time had not elapsed to show any improvement, we find that including the two recurrences, we had ten primary, eight secondary, and four tertiary lesions, one of which was a periostitis of both tibia, one a rupial syphilide, and two gumma of the palate.

Of the ten primary lesions one healed after two injections, three healed after four injections, one was healed at discharge after receiving six injections, and one was healed at discharge after receiving seven injections.

Two patients having received only two injections, one patient with four injections, and one with seven injections, were noted to be recovering when they voluntarily left the hospital.

Of the eight patients with secondary lesions one recovered after three injections, four recovered after four injections, two recovered after five injections, and one recovered after six injections.

Of the four tertiary lesions, in the case of periostitis the patient was improved with only two injections, the case with rupiæ cleared after four injections, and in the cases of gumma of the palate the patients received two and nine injections, respectively, and were discharged improved.

This brings us up to a statement in regard to doses of the drug, and reactions to it.

When we first began using mercodel we gave somewhat larger doses than we do at the presen time. We began with twenty or twenty-five c. c. which represents two hundred or two hundred and fifty mgm. of mercury, and attempted to increase the dose five c. c. with each injection, to a maximum of fifty c. c. a dose, and very soon discovered that this intensive treatment nearly always provoked abdominal cramps, diarrhea (sometimes bloody), stomatitis, gingivitis, and salivation, although there never were any nitritoid crises nor anaphylactic shocks. We now begin with five or ten c. c. of the mixture, representing fifty or one hundred mgm. of metallic mercury, injecting twice a week, and increase the quantity with each subsequent injection until we produce salivation or gingivitis, at which point we hold the dose until the patient's tolerance increases. Rarely is it necessary to discontinue the drug because of these latter symptoms.

Of the twenty-seven patients, eight presented no symptoms whatever—of these, four received only one injection, two received two injections, one received three injections, and one received seven injections. Of the remaining nineteen patients, ten showed either slight stomatitis or gingivitis, and one a marked stomatitis. Diarrhea to a mild degree was apparent in six cases, and to a marked degree in two cases, in one of which there were bloody stools after the first injection only, but not after any other injection, in spite of the fact that the quantity was increased.

Uranalyses were done in all cases twice a week. In no instance did there appear more than a faint trace of albumin—ten cases—in four of which this was exhibited in only the first or second specimen. The other six were negative upon discharge of patients from the hospital. A few hyaline or finely granular casts appeared three times, but were absent when the patients were discharged.

Cole (8) states that thrombosis of the veins was one of the greatest drawbacks to the administration of this drug. A large number of our injections were given by various of the hospital interns under the supervision of either one of us, and we can definitely state, that while we saw thromboses in several instances, it never occurred in this series in a case where we had not the knowledge, definitely, that the technic had been imperfect, either the vein having been injured by the needle, or actual infiltration with mercury having occurred. However, in one case not included in this series a patient receiving his injections in the alternate arm each time, had thrombosis occur after the seventh injection in each arm, i. e., after the thirteenth and fourteenth injections. This represents the only case of true thrombosis seen.

CONCLUSIONS

1. It is possible to administer a larger quantity of mercury in a shorter period of time by this method than by the use of the soluble salts.

2. The lesions disappear at least as rapidly under the administration of this drug as with any other now being used.

3. The smallest number of injections which produced any change in the serology was seven, representing 1.03 gm. of mercury. The smallest quantity of drug showing any serological change was 0.85 gm. given in nine injections.

4. Stomatitis or gingivitis in mild forms is a quite common sequel to the administration of the drug, but does not become severe under the principle of the smaller doses, if this dose is not increased while the symptoms are present.

5. While traces of albumin and a few casts may appear in the urine, they will disappear either under a continuation of the treatment, or promptly upon discontinuing it.

6. Thrombosis did not occur in this series in any instance where the technic was unimpeachable, although we have seen it occur twice in another case after the seventh injection in each vein.

7. We believe this mercurial to be potent, safe, and worthy of further trial.

We wish to express our thanks to Dr. Alfred Potter for allowing us to administer this drug to the patients on his service, and also for helpful suggestions during the preparation of this paper.

Vaccine Therapy.—C. Bucura (*Zentralblatt für Gynäkologie,* August 2, 1924), found the result of treatment for gonorrhea and other inflammatory diseases of the female genitals very satisfactory in the large majority of cases, but not always ideal. The initial dose of 100 million bacteria, that is 0.1 c.c. of the vaccine, is given in the substance of the vaginal portion of the cervix and every accessible gonococcus focus is treated locally at the same time. The treatment includes also physical methods in the form of baths, diathermy, quartz lamp therapy, caseosan, aolan, electrargol and milk injections. If a reaction sets in after the first injection, the next injection is given one or two days after the reaction has entirely subsided and the same dose is continued until a reaction is no longer produced. The dosage is then always increased by one hundred million bacteria. A dose of more than six hundred million bacteria was never found necessary and never given. The gonococcus vaccine used by the author contained one thousand million gonococci to one c.c.; the mixed vaccine contained one thousand million gonococci, one thousand million staphylococci, two thousand million colon and bacilli and twenty million streptococci to the c.c. The mixed vaccine was given either when the gonococcus vaccine was found valueless or from the very outset in inflammatory diseases when gonorrhea could be definitely excluded.

The contraindications for vaccine therapy, especially with mixed vaccine, (simple gonococcus vaccine is rarely contraindicated) include all inflammatory and suppurative processes in other important organs (active apical processes, cavities, severe bronchitides, suppurating sinuses, etc.) as well as severe cachexias.

The criterion of a cure includes complete absence of clinical symptoms and negative microscopical bacteriological findings in the secretions during a period of observation of two, or better, three months, with at least three examinations per month—postmenstrual, in the middle period between two menstruations and just before menstruation.

Treatment of Hyperidrosis and Bromidrosis of the Extremities.—Clottens (*Bulletin de la Société des sciences médicales de Montpellier,* February, 1924) notes that the measures commonly employed, such as applications of diluted formaldehyde solution, saturated picric acid solution, absolute alcohol or 1:20 chromic acid solution, bathing the feet in lead subacetate solution or three per cent. potassium permanganate solution, and the use of tannic acid or alum powders, are only temporarily effective, the layer hardened by these agents dropping off in fifteen to twenty days, leaving a macerated layer which requires renewed treatment. For such maceration, a simple procedure popularly advocated in Flanders is effective, viz., sprinkling sifted wood ashes in the hose. The activity of fermentative bacteria is combatted by cleanliness and the use of powders of salicylic acid and talcum. In bromidrosis the fetor may, no doubt, be partly of bacterial causation, but in true bromidrosis it is primary, hard to overcome, and often a family peculiarity. The author recommends in these cases a combination of four parts of formaldehyde to ninety-six parts of creosote. This is dusted daily in the hose and between the fingers. Decomposing gradually into its two components, this combination markedly reduces the hyperidrosis without "fixing" the skin. Maceration of the feet is checked and even the deepest interdigital excoriations are cured in a short time. The microbic flora is inhibited. The remedy may also be of service in similar disorders; thus, among others, it was used with success in a case of intertrigo in a stout woman.

Cocaine, Butyn, Tutocaine, and Other Local Anesthetics.—The experiments of A. J. Copeland (*British Medical Journal,* July 12, 1924) show that the best of the local anesthetics for the eye are cocaine and butyn. Tutocaine may also have a use. Tropacocaine, novocaine, and eucaine are less valuable for deep anesthesia. For the nose, cocaine and tutocaine are alone useful. For subcutaneous injection novocaine is much the best. Besides cocaine, it is believed that the properties of butyn and tutocaine may render them addiction drugs.

A Study of Eighty Cases of Acne Treated With X Rays

LAWRENCE K. McCAFFERTY, M.D.,
and C. LEE McCARTHY, M.D.
New York

The question arises whether the application of x rays when used in a proper manner exert a harmful influence upon the skin or not. In this article it is proposed to outline the different types of acne and to give the results of the combined treatment (x rays, local application of medicaments, etc.), together with a consideration of any harmful results that may occur. The experience of the past few years has taught all dermatologists that x rays are the most successful local agent in treating acne.

It is generally accepted among dermatologists that the acne bacillus is the etiological factor; whether we accept Sabouraud's (1) view that the acne bacillus (microbacillus) causes only the comedone or Gilchrist's (2) view that the acne bacillus may cause all the characteristic lesions of this condition, is a matter of opinion. The acne bacillus is present on every normal skin after puberty. The characteristic lesions of this condition, as we know them, are usually found in individuals whose normal resistance has been lowered. Therefore, it is unwise to rely exclusively upon x rays to eradicate permanently a condition which is initiated probably by constitutional derangement.

CLINICAL TYPES

The clinical picture of acne vulgaris is too well known to occupy time and space except to state briefly the classification followed in the charts. The comedone occasionally predominates exclusively but usually we see the mixed type consisting of comedones, papules and superficial pustules. On the other hand instead of the superficial pustules there may be brownish red dermic abscesses or indurated lesions. Less often we see what Brocq (3) describes as *acné mentonnière indurée profonde,* which is a papulopustular acne confined to the chin, usually occurring in women between twenty-five and forty-five years. There are usually five or six lesions appearing in an uninterrupted succession; after the complete involution of one lesion another begins. The French school believes this condition closely allied with disturbances of the uteroovarian organs or the nervous system. Bazin (4) has described an acneiform eruption due to the ingestion of certain medicaments, principally the iodides. Although this condition is well known to all physicians the possibility of its occurrence must be kept in mind for it may closely simulate a true acne vulgaris. Occasionally recourse to the history may be necessary in order to differentiate between them. It was thought advisable to include acne rosacea in our discussion of acne vulgaris because of its similarity in reaction to x rays, as well as the closely related contributory factors in the two diseases.

X RAY TREATMENT

It is unnecessary at this time to trace the history of x rays in acne as it has been recently chronologically stated in an article by Howard Fox (5). Suffice to say that Gautier (6) reported the first case treated by x rays: numerous French and German writers followed him. In America Hyde, Montgomery and Ormsby (7), Pusey (8), Engman (9) and others were early workers in this field of therapy. At the present time our dose may be accurately measured, due primarily to the arithmetical formula of Remer and Witherbee (10). With this increased knowledge of radiotherapy, with a proper technic and approximately sixteen treatments we may fairly well ascertain the end result of our acne cases. MacKee (11) in his book has stated so clearly the procedure, dose, etc., that the treatment has been greatly simplified. He has always insisted upon one quarter unit doses to each cheek weekly. The best results are probably obtained by this dose. It is safe and perhaps should be adopted by all dermatologists if for no other reason than to control results in transient patients. Whether to use astringent lotions or not during irradiation is still questionable. As a rule we have not done so; on the other hand, Wise and Eller (12) have used them without any harmful effects.

The accompanying chart which is discussed later on, comprises eighty cases in which the patients were treated privately by us. In each patient the clinical type, focus of infection and recurrences were noted, as well as the duration of the condition, age, sex, etc.

The most important question is the number of recurrences following x ray treatment. In this group

Fig. 1.—Severe case of acne indurata completely cured after sixteen x ray treatments.

of patients there were ten per cent. of recurrences. This includes all types of acne excepting acne rosacea and acne varioliformis. The word recurrence here is restricted to the appearance of several comedones, papules or pustules occurring three weeks to three months after the last x ray treatment. Where cooperation could be obtained astringent lotions were begun two weeks after the last x ray treatment. The number of recurrences were less in this group. It is understood, of course, that a few papules just preceding or during menstruation are not to be considered a recurrence, for this may be the usual occurrence in normal women. Of the eight cases which recurred six were later satisfactorily cured by further röntgenization, but the remaining two had to be considered improved rather than cured.

It is always advisable in acne to follow x ray at the end of the course of irradiation by local treatment. Any one of the well known astringent lotions may be used. The patient should produce a slight peeling or roughening of the skin for six to eight months. The strength of the lotion must be increased from time to time.

The average number of x ray treatments in our series may be placed at sixteen; that is, exposure weekly to one quarter unit doses for sixteen weeks. Occasionally it was necessary to give a one quarter unit to each cheek and one eighth unit to the front of the face. Some patients may require a few less and others a few more. It is not advisable, however, to exceed eighteen quarter unit doses in a single course unless the acne is upon the chest or back. An exception may be made if the patient is a male, brunette, with a severe indurated type and shows no perceptible skin change. However, it has been our experience that the indurated type of acne responds most quickly and therefore extended treatment is usually unnecessary.

The danger of too many exposures is a disagreeable dryness or perhaps wrinkling. MacKee does not believe telangiectasia may occur unless an erythema has been produced. In his series he has never seen telangiectasia nor radiodermatitis develop. He noticed, however, ten patients with slight wrinkling. In our series no telangiectasia has ever been noticed but in two patients a dryness became evident after eight and ten treatments, respectively. These patients were receiving one quarter unit doses to each cheek weekly. When the dose was decreased or the interval lengthened the sebaceous glands soon became reasonably active and the skin lost its disagreeable dryness. On the other hand, the skin was never as oily as formerly; this, of course, is the desired result. In some patients we found that wiping the face with pure grain alcohol twice daily removed the excess oil.

In fifteen patients the acne was so pronounced that it was necessary to give one eighth unit doses to anterior portion of the face and one quarter units to each cheek. Two of this number exhibited slight wrinkling but they themselves were not aware of this. This wrinkling did not occur until several months after cessation of irradiation. It is interesting to note that after the fourth weekly treatment in one and the fifth weekly treatment in the other a faint erythema appeared. The machine was carefully checked and a search made for faulty technic, but nothing was found. Nor were other patients affected in a similar manner at this time. We discontinued treatment for two weeks and then proceeded more cautiously, applying only eighth unit doses to each cheek and not x raying the front of the face. Later quarter unit doses were given to each cheek at weekly intervals with no further erythema. These patients were both blondes and received sixteen treatments in all. We must conclude from this that faint erythema may be

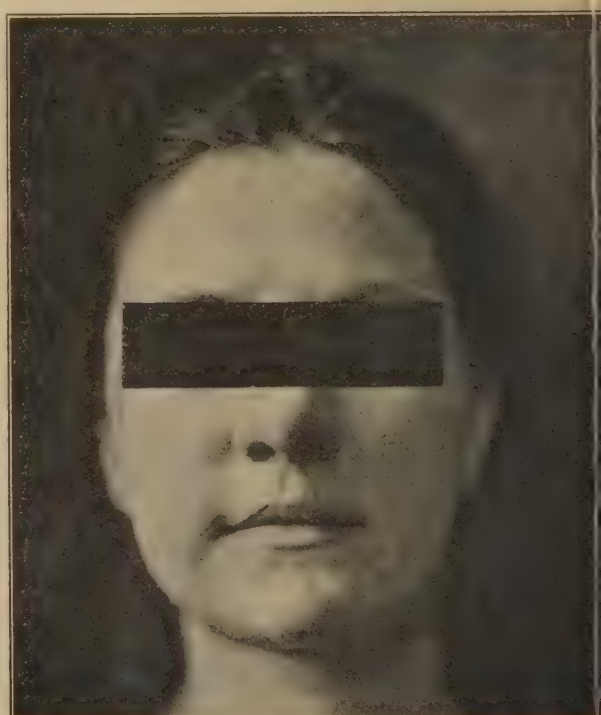

Fig. 2—Front view of patient shown in Fig. 1 after sixteen x ray treatments.

FIG. 3.—Case of comedo type of acne with some papules. X ray treatment of this type gives excellent results.

roduced by this dose (one quarter unit to cheeks nd one eighth to front of face) in certain susceptible ersons.

We believe that this early erythema had a causal elation to the subsequent wrinkling or atrophy. Mac-ee states that in one patient there was clinical atro-hy without telangiectasia two years subsequent to mild first degree reaction. Atrophy or wrinkling nay also result from long continued fractional treat-nent but the usual course of sixteen treatments, pro-ided no erythema appears, does not in our opinion roduce atrophy.

However, one should always be on the watch for n erythema. The patient's skin should be examined efore each exposure and if erythema is noticed all reatment should be suspended for at least three veeks. After this interval one should proceed cau-iously, giving only eighth unit doses to each cheek veekly. If no erythema appears the standard frac-ional dose may be given. If attention is paid to hese details, and if we bear in mind the occasional ypersensitiveness to x rays, disagreeable results may e avoided. The treatment of acne by x rays may ow be considered our best therapeutic agent in this hronic and disfiguring disease.

The chart indicates that the greater incidence was mong females but we believe these figures taken rom private practice to be erroneous. It is our pinion that both sexes are equally affected but vomen seek relief more frequently than men.

Since acne is a disease manifesting itself at puberty t is natural that there are many more cases among ingle persons than among the married. Our chart hows ninety-three per cent. among the unmarried. n the same series sixty per cent. of those with acne osacea were married. This is to be expected when ve note the average age was thirty years. The question often arises whether the patient will outgrow acne vulgaris. Frequently, if it is quite mild, they may, but usually it progresses, leaving the face disfigured by scars. Marriage will not cure acne. If masturbation has been practised a normal marriage may alleviate it, but in general the condition progresses until some definite treatment has been adopted. It is essential to treat acne early if the best results are to be obtained.

FOCUS OF INFECTION

Every patient should be carefully examined for possible foci, particularly teeth, tonsils, sinuses and the gastrointestinal tract. One of us has seen an acne recur after two courses of x rays only to be permanently cured by the extraction of a devitalized abscessed tooth. Where devitalized or gold crowned teeth are present radiograms should be made and a rational decision reached by dentist and radiographer. Smelhaus (Prague) (13) reports four cases of acne in which the eruption promptly disappeared after the cure of necrotic disease of the tooth pulp. Only when the pulp is necrotic, however, is a connection between disease of the teeth and acne to be taken for granted; the acne is caused by products of putrefaction entering the intestinal canal. In cases of acne in which the pulp was intact or only inflamed (not yet necrotic), treatment of the teeth was without results. We do not advise enucleation of tonsils unless there is definite evidence of disease and this should be left to the judgment of the rhinolaryngolo-

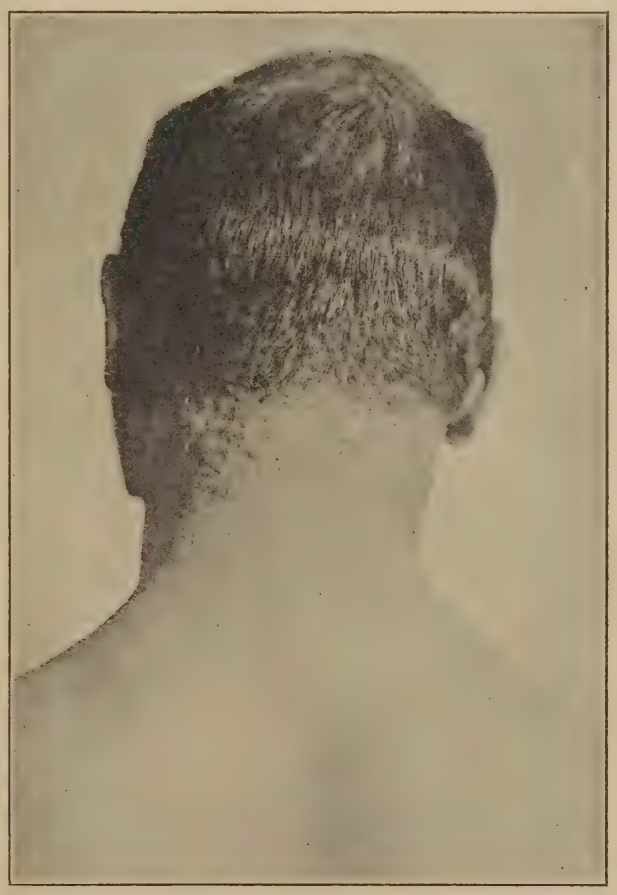

FIG. 4.—This was a severe case of acne indurata followed by keloidal lesions. Note destruction of hair follicles. Cured after twenty x ray treatments.

gist. Usually mild laxatives and carbohydrate free diets will suffice but occasionally it will be necessary to examine gastric contents and intestinal tract for the causation of chronic constipation and autointoxication. Ketron and King (14) a few years ago examined a series of thirty cases of acne vulgaris from the gastrointestinal point of view by means of test meals and fluoroscopic observations. They found that none of them gave absolutely normal findings and that sixty per cent. of the cases showed abnormalities which were of such nature as to permit gastric and intestinal stasis followed by toxic absorption. Recently, however, Ketron stated to us that he was not so sure the normal individual might not show the same findings.

What rôle the endocrine glands play in acne is undetermined. As Timme (15) states, "During the period following menstruation when the corpora lutea are formed, there is usually a diminished thyroid activity. As this period of luteal activity wanes and the next menstrual period approaches, the thyroid, presumably less opposed, becomes overactive and the nervousness, excitability and general mental uneasiness produced by thyroid activity becomes manifest." One might add to this that there is an accentuation of the acne and in the normal individual we often see the appearance of a few acneiform pustules during this period. As the French have pointed out there is an increased basal metabolism in hyperthyroidism and also in acne vulgaris during this period. We occasionally see acne confined to the chin in young women who give a history of irregular menstruation or dysmenorrhea. When such cases do not respond quickly to x rays or when the lesions recur one may administer ovarian gland with the purpose of balancing a hyperactive thyroid. In one of our cases of *acné mentonièrre* this type of therapy was successful when x rays failed completely. We do not advocate the indiscriminate administration of glandular therapy in acne but believe the future may be bright in this form of therapy.

In our series of cases of acne rosacea we have permanently cured ninety per cent. of our patients. Each patient presented the characteristic eruption which had lasted from three to ten years. We found in six patients a marked pyorrhea and abscess formation on devitalized teeth. One patient had a chronic sinusitis. One patient had dental abscesses and hyperchlorhydria. Two others presented simply hyperchlorhydria. One had a chronic prostatitis while in another the history and examination revealed nothing except a very rich diet. By proper treatment in the hands of specialists and x rays locally nine out of the ten cases were permanently cured. The acneiform lesions in the tenth case disappeared but the nose remained red. Some of this redness was removed by the destruction of superficial vessels with the electric needle. These results may illustrate how important it is to search for foci of infections.

Vaccine therapy apparently has had its day in acne. Howard Fox (5), who interrogated many of the leading dermatologists recently regarding vaccines in acne, came to the following conclusions: "Stock and autogenous vaccines are considered by the majority to be of equal efficiency. Whatever value these vaccines may possess is restricted to their use in selected cases, chiefly of the pustular type, or as an adjuvant to other methods of treatment. The action of vaccines is slow and improvement is often temporary. In the treatment of acne vulgaris, the röntgen ray is far superior to vaccines." We quite agree in so far as our experience goes with the foregoing summary. However, some of the early workers in this field cited some brilliant results from the use of vaccine. In the hands of these men, who were trained bacteriologists (16) as well as dermatologists, we do not believe that the efficacy of vaccine therapy can be entirely denied. However, the simplification of the method of the application of x rays and the limitation of its use to trained hands, has replaced vaccines and perhaps relegated them to the past.

Clinical type	*No. of cases*	*Average age years*	*Male*	*Female*	*Single*	*Married*	*Average No. of treatments*	*Cures*	*Recurrences*	*Cured after recurrence*	*Average number of treatments after recurrence*	*Not cured but improved*	*Remarks*
Comedone	11	18+	21	42	11	0	18	9	2	2	8	0	There was an almost total absence of comedones after x rays.
Papulopustule	35	18+	—	—	34	1	16	32	3	2	6	1	Cosmetic result very good.
Acne indurata	17	18+	—	—	15	2	18	15	2	2	8	0	Some scarring in all cases. Kromayer light with pressure improves this scarring.
Acné mentonnière induré profonde	7	22	0	7	5	2	14	6	1	—	8	1	Administration of ovarian gland caused disappearance of all lesions.
Acne rosacea	10	30+	3	7	4	6	16	9	1	—	6	1	Electric needle caused obliteration of venules but some redness remained.
Acne varioliformis	1	18	—	1	1	—	12	1	1	1	5	0	

SUMMARY

1. X rays are the most valuable therapeutic agent in acne.

2. Sequelæ in the hands of experienced men are practically nil.

3. For the best end results careful attention should be paid to focal infection, pathological disturbances, and dietary errors.

4. Vaccines are unnecessary (except in the occasional case) when irradiation is begun.

The Significance of Heredity in Diseases of the Skin

NORMAN TOBIAS, M.D.
St. Louis, Mo.

Heredity has long been known to be a factor in the etiology of certain cutaneous diseases and malformations but the practical aspects of the subject have been neglected to a great extent. Since James C. White delivered his paper on the "Hereditary Dermatoses" before the International Congress of Dermatology and Syphilis in Paris in 1889, studies and investigations have accumulated and have been analyzed in many cases to explain some of the phases of human heredity in dermatology.

The difficult problems of human heredity have been especially studied by Davenport, Morgan, Thomson, Popenoe and Johnson and many others. In ophthalmology, Nettleship and Howe should be mentioned; in psychiatry, Goddard, Rosanoff, Cotton and others; and in dermatology, Siemens, Stainer, Davenport and his coworkers.

Unfortunately civilization has interfered with the student of human heredity in many ways. The laws of heredity which apply so well to plants and animals meet opposition when conditions in man are studied. This is principally due to the limited size of families, the absence of brother and sister marriages, slow propagation, late maturity and the difficulty of securing reliable data. The first law of heredity, the phenomenon of "segregation of characters," if it could be applied to man, would add greatly to our knowledge of human inheritance. The Austrian monk, Mendel, showed in 1866 that when two opposite characters are crossed, only one of the characters appears in the offspring. This character is termed the dominant and the suppressed character the recessive. If the products of the first filial generation (hybrids) are mated, both characters will appear in the offspring, thus demonstrating the segregation of characters. It is here that the application of the Mendelian law meets opposition since it thus would necessitate the crossing of persons of the same parentage.

We must therefore depend upon other methods for ascertaining the inheritance of human characteristics. As Walter aptly states, "the consideration of human heredity must always be largely from the statistical side, consisting in an analysis of experiments already performed rather than in arbitrarily initiating new experiments." The results of these experiments are available in our large hospitals, clinics and institutions.

FACTORS RETARDING THE STUDY OF GENETICS IN MAN

There are several factors that modify and retard the study of genetics in man. Wells has recently stressed this subject in relation to the heredity of cancer. These adverse conditions may be classified as follows:

a. Unreliable family and ancestral histories.
b. The opportunity for error in the diagnosis of the attending physician.
c. The element of chance in the reappearance of a disease.
d. The inability to utilize plants and animals in this study.
e. The lack of control over human reproduction, mating and survival.
f. Inaccurate and missing birth records.
g. The inability to locate certain families and individuals.

IMPORTANCE OF HEREDITY IN CONGENITAL SKIN DISEASES

It is impossible to conceal the importance of heredity in the etiology of many congenital affections of the skin. While perhaps of more significance in psychiatry and ophthalmology, nevertheless, certain disfiguring affections of the skin, hair or nails may be the cause of great concern to the patient. Similar to what Howe has done in ophthalmology, the following data must be collected to aid the dermatologist in the application of heredity to his special field:

a. Compilation of a complete and modern bibliography.
b. Classification of titles according to diagnoses.
c. Addition of accurate family histories of skin defects.
d. Comparison of the relation of such tables with the Mendelian or other principles of heredity.
e. Stressing the importance of the differential diagnosis between those defects which are truly

hereditary and those which are due to infections.

f. Suggestions for measures to prevent or restrict the hereditary diseases.

HEREDITY IN DERMATOLOGY

During the last ten years there have been many contributors to the literature on the heredity of cutaneous diseases. Among these may be mentioned Meirowsky and Bruck and Siemens who have written on general discussions of the subject, Davenport and Preiser on neurofibromatosis, Dorothy Osborne on alopecia, Buchanan on protein sensitivity, Knowles on psoriasis and Levin, Maud Slye and Wells on carcinoma in general.

Among the conditions that have been shown to be transmitted as dominants may be mentioned the following: ichthyosis, keratosis palmaris et plantaris, multiple neurofibromatosis, monilethrix, ringed hair, gray locks, congenital alopecia, atrophia unguium and persistent hereditary telangiectasia.

Albinism, epidermolysis bullosa and carcinoma (in mice) appear to be transmitted as recessive characters. The heredity of psoriasis, acne, diseases due to protein sensitization, and the nevic types of malformations has not yet been completely worked out. The work of Siemens in his study of abnormalities in twins tends to disprove the assumption that birthmarks are inherited.

The inheritability of psoriasis has received considerable attention in the past although most dermatologists at present favor the parasitic or infectious theory as the cause of the disease. Psoriasis is a very common skin disease constituting from two to four per cent. of all cases. Stelwagon believes its frequent occurrence strengthens the parasitic theory while Ormsby states that there is an inherited predisposition in a number of cases although direct transmission of the disease has not yet been demonstrated.

MacLeod, an exponent of the microbic theory, also is convinced that an inherited predisposition to the disease exists, somewhat analogous to that which occurs in tuberculosis. The inheritance of a suitable soil for the growth of the unknown parasite may be a factor in many cases. Engman's report of fourteen cases in six generations is interesting from this viewpoint, although Knowles examined the histories of hundreds of cases and found only six instances of the familial type.

McNair has studied the heredity of rhus dermatitis and believes that resistance to the disease may be a dominant character. He has applied the Mendelian law to explain the appearance of high susceptibility in some families, immunity in others, varied susceptibility in individuals of one generation, immunity in one generation and susceptibility in the next.

Fasold has recently studied the heredity of xanthoma and finds it a dominant characteristic although the transmission is particularly irregular.

It is possible there is an inherited predisposition or constitutional state behind every disease controlling or modifying the type and extent of the pathological process as well as the resistance and susceptibility of the patient. Dermatologists have long recognized seborrhoic types of skin and the exudative diathesis. The French school of dermatology especially stresses constitutional types.

The internal secretions also may be involved in the complicated process of heredity. Thyroid therapy occasionally brings about improvement in certain cases of ichthyosis and nail diseases. Since the heredity of blood groups has been proven, certain states of the blood may be a factor in the production of certain hereditary skin diseases.

SUMMARY

1. Plant and animal experimentation is impossible in the study of human heredity so that investigations must largely be from the statistical side.

2. Certain disfiguring diseases of the skin that are hereditary should be studied more thoroughly from the viewpoint of genetics and eugenics.

3. A few diseases of the skin have already been classified as to their dominant or recessive characteristics.

Case After Operation for Extensive Burn of the Left Lids, Eyeball, Upper Face and Temporal Area*

J. EASTMAN SHEEHAN, M.D., F.A.C.S.
New York

On October 2, 1922, the patient, A. D., while leep in his room in a Pennsylvania city, was atcked and burned with carbolic acid. The fact that was not the person for whom it was intended did ot save him any of the discomfort. He was treated a local hospital, and afterwards, March 3, 1923, e came to the Post-Graduate Hospital, New York. On admission it was found that the face was much lcerated and extremely sensitive; the temporal area was still worse, the acid having destroyed the structures down to the bone; the hairy area on that side was destroyed, with foul smelling pus exuding; the eyeball was irreparably injured and hanging loose from its moorings; and the area about the lids was sloughing. Altogether a dreadful and seemingly hopeless condition.

Attention was first directed to combating the infection. By April 13, 1923, sufficient progress had been made to warrant the removal of the lid gland (done by Dr. Martin Cohen) and the repair of the eyelid by epithelial onlay. This operation was successful, function was restored to the lid and a good appearance resulted.

On May 5, 1923, the lower lid and upper face area were repaired by utilizing a supraorbital artery skin flap from the forehead, the upper border of the flap carrying a margin of forehead hair to replace the loss of the lower eyelashes.

On May 29th, repair of the temporal area was undertaken. A tubed flap from the scalp was brought to restore the destroyed hair area, and included with it was a section of skin from the nonhairy postauricular area for repair of the cheek. The patient's condition was not of the best for some time afterwards, and no other operation was performed until October 18th, when the supraorbital pedicle was re-

turned to the forehead. On October 26, 1923, enucleation of the eyeball was made by Dr. Cohen, and later on an artificial eye was inserted. On November 9, 1923, the scalp flap pedicle was returned, this being the fifth and final operation, during which the blood conditions occasioned some anxiety.

Healing was complete in December, 1923. The patient wrote, "I am as near my natural self as it is possible to get. I am at home feeling healthy and happy." Some time afterwards he returned to the occupation in which he had been engaged before the injury.

636 Fifth Avenue.

Clinical Value of the Vasomotor Reflexes of the Skin*

EDWARD A. TRACY, M.D.

Boston, Massachusetts

This communication, prepared primarily in answer to a recent criticism of Sampson Wright on a paper on "The Normal Reaction of the Skin to Stroking," published by me in 1916 (1), may also serve to draw attention to the diagnostic value of the vasomotor reflexes of the skin. Wright's paper, entitled "Some Observations on the Nature and Diagnostic Significance of the White Line of Sergent (*Ligne blanche surrenale*)," not only denied any pathological significance to the white line, but in addition would seem to have demolished the work reported in my 1916 paper, namely the phenomenon observed and described as the normal reaction of the skin to light stroking.

It is not so easy to kill two birds with one stone, and in attempting it a boomerang technic should be carefully avoided.

In his paper Wright states that he carefully followed the directions of Sergent in producing his white line, and the paper itself shows that he read Sergent's later communications (1921) on the subject. Had he treated my work as consistently, in the first place, he would have used the technic prescribed in Tracy's paper to get the phenomenon first recognized by him as the normal reaction of the skin to stroking (lightly); and second, he would have learned from the later communications that the white line has pathological significance.

1. Wright did not follow the prescribed technic, as the following excerpt from the paper he criticizes evidences. "The deduction that the phenomenon here described is the normal reaction of the skin to a mechanical irritant is based on the fact that it was observed in 1,165 out of 1,236 subjects examined. Their ages ranged from six days to eighty-three years. As there were known disease conditions in the majority of the remaining cases, it strengthens the deduction that the phenomenon under consideration is the normal reaction. The phenomenon in brief is this: When the skin of a normal quiescent subject is stroked by a wooden instrument (e. g., a wooden tongue depressor or a match) it reacts by a deepening of the skin tint, generally brief in duration, appearing where the stroke was made, or in its immediate vicinity, and then, after a period of fifteen seconds, by a longer lasting whitish color (in Caucasians), showing itself in the location where the stroke was made. The reaction is seen most clearly when the test is made for it on the rosy cheek of a healthy Caucasian boy or girl. The cheek is lightly stroked across once; its tint where stroked is soon seen to deepen, and, after fifteen or more seconds, a pallor takes the place of the redness, the streak of white being very noticeable because of its contrast with the rosy field upon which it is displayed. The normal reaction just described consists then of two components, the one, vasodilatation, and the other, vasoconstriction."

Wright (2) states in his paper: "I am unable to confirm Tracy's observations." Why? The reason is obvious on reading the following extract from his paper: "The technic adopted was as follows. After the clinical history had been taken, the subject was placed in a recumbent position for some minutes with the abdomen free, but lightly covered. A geometrical figure was then lightly traced on the skin of the abdomen with the round smooth end of a fountain pen. The directions of Sergent were closely followed. No pressure was exerted."

That the reaction from stroking the skin without pressure with the round smooth end of a fountain pen and the reaction obtained by stroking it lightly with a match or a wooden tongue depressor differ, any one will find by testing. The failure to use the prescribed technic accounts for Wright's failure to observe the beautiful reaction he would have seen had he stroked with a match the cheek of a healthy child, the reaction of brief vasodilatation followed by longer lasting vasoconstriction; a reaction also capable of verification by the careful observer.

May it be noted that notwithstanding Wright's "careful examination of the literature" one misses from his summary review the paper of M. Karasawa (Tokio) (3) in which this reaction to light stroking is described though not recognized as the *normal* reaction: "At the request of Th. Eserich," writes Karasawa, "I have sought the white line in healthy and diseased children. The test was made by stroking delicately the skin with a thin piece of metal. After a few seconds the skin became light red in the place stroked, then later (after ten to sixty seconds) in positive results the white line appeared. The reaction disappeared after three to six minutes." An additional item of interest is that Karasawa in his paper referred to a white line described by Bonchut in 1862, that antedates by thirteen years the earliest white line mentioned in Wright's paper, that of Vulpian, 1875.

* From the Clinic for Nervous and Epileptic Children, Forsyth Dental Infirmary.

The failure of Wright to observe the phenomenon described in the writer's communication as the normal reaction to stroking the skin (lightly) is therefore readily explainable: he ignored the prescribed technic and used one unsuitable for the production of the phenomenon.

2. Wright did not follow up in the case of Tracy (as he did in the instance of Sergent) the work reported in later communications. In one such communication, "A Method of Testing the Vasomotor Reflexes of the Skin and of Recording the Same" (4), published in 1917, he would have read:

"All somatic phenomena are worthy of investigation and tabulation. In this way we learn to distinguish accurately what is normal from that which is abnormal. When certain abnormalities are found associated with certain disease conditions we are helped in the diagnosis of these conditions by the presence of the abnormalities.

"In studying the reactions in the peripheral bloodvessels caused by light stroking of the skin, I came to testing both sides of the face and both forearms (as these parts are readily accessible) and to record the findings in the time saving manner described below. In a normal person, when the skin is lightly stroked (with a pressure of about two ounces) there appears on the stroked surface a deepening of the skin tint lasting up to eight or twelve seconds, and then a white streak appears that lasts for a couple of minutes."

After describing the method of testing both sides of the face and both forearms, the paper continues as follows: "This method of testing the vasomotor reflexes was employed by the writer in the hope that the study of the phenomena in this systematic manner might lead to some useful result. Nor has the hope proved fruitless. A study of the reactions in normal and diseased individuals has already led to important findings of use in diagnosis. The method is offered to the clinician that tests may be made and recorded methodically in various diseases. A larger knowledge of the phenomena of the vasomotor reflex will thus result, etc."

Had Wright supplemented the reading of my first paper by a perusal of this communication printed in 1917, he would have seen that the use of a measured stimulus is insisted upon in passing. The more the subject is studied the more one recognizes the necessity of a measured stimulus in evoking the vasomotor reflexes of the skin, for the self evident reason that reactions vary with the amount of stimulus used to evoke them: unless a measured stimulus be used there is not identity of the phenomena under investigation. To the lack of a measured stimulus in evoking skin reactions is attributable, no doubt, the discordancy between observations made by different observers, and the controversy among clinicians over Sergent's white line.

When we measure the temperature of a patient, we do not rely upon our tactile sense, we use a thermometer. Likewise in measuring the pressure that serves as a stimulus in evoking the vasomotor reflexes of the skin, it is better to do so by means of an instrument, which in its very nature is devoid of the personal equation that inevitably accompanies the measurement of a stimulus by the tactile sense. A small spiral spring with a piece of a wooden tongue depressor inserted in one end has served the purpose admirably; it is so constructed that it evokes the reflexes with a measured stimulus approximating two ounces.

Although in my first paper no specific mention was made of a measured stimulus, as a matter of fact a stroke approximating two ounces had been employed. The discovery of the normal reaction to stroking the skin was the result of considerable investigation: the phenomena evoked even in normal subjects were so various that it was not until I hit upon a certain light stroking that the phenomena evoked in normal subjects were seen to be constant. This particular stroking when measured later, was found to be from two to two and a half ounces, and, realizing the necessity for specifying this amount of stimulus for scientific clinical work, its employment was specifically directed in after communications.

If the postulate be granted that a measured stimulus must be used in evoking skin reactions in order that these may have scientific value, it is difficult to see what value Wright's paper can have since unmeasured stimuli were used in producing the phenomena reported. That vasomotor reflexes evoked with a measured stimulus, certainly have important clinical value, two of my later communications were intended to demonstrate. One of them is devoted to the investigation of reflex vasodilatation, the first component of the normal reaction to stroking the skin; the other is a study of epilepsy, in the course of which the second component of the normal reaction, i. e., reflex vasoconstriction, or the white line, is shown to have pathological significance.

The first of these papers, entitled "The Red Streak: A Sign of Disease" (5), showed that reflex vasoconstriction (the first component of the normal reaction) evoked with a measured stimulus (two ounces pressure) when it lasted longer than fourteen seconds on the face, is pathognomonic, a sign of disease present in the individual tested, generally a purulent disease. Among the many disease conditions reported in which the "red streak" was found is mentioned cerebral meningitis, and Trousseau's famous diagnostic sign *la raie meningitique* is identified as a pronounced pathological lengthening of the reflex vasodilatation that is the first component of the normal reaction of the skin to stroking.

Another disease condition in which the red streak was found is socalled nervous or irritable heart. Since a part of the paper contains observations *evidencing* the involvement of the vegetative nervous system in the vasomotor reflexes (an involvement originally assumed to explain rationally the phenomena observed and reported) it is here copied:

"Functional heart cases, socalled nervous heart, are found associated with the red streak. Twelve cases were met with and tested. All gave the red streak. In four of these, the phenomenon of partial fading and intensifying of the streak, i. e., active systole and diastole of the peripheral bloodvessels, was visible. This phenomenon, so far as I am aware, has not been observed before; at least I have met with no account of it in the literature. In one case in which this phenomenon was noted, at the same time there were present reduplication of the heart sounds and irregularly acting heart. Some weeks after, on examining this case again, the red streak was present,

but the active systole and diastole of the vessels forming it were absent."

As regards the red streak with nervous heart disease, Lian (6) has made a similar observation: *"Coeur irritible—Symptomes connexes: Troubles vaso-moteurs. . . . Lorsqu'on explore la sensibilité du cou ou du tronc avec une épingle, on provoque, en general, l'apparition de petits points, ou de petites eleveurs rouges. La peau reagit d'une facon analogue si on trace une raie avec l'ongle."*

The second of the papers referred to, reporting the investigation of the second component of the normal reaction of the skin to stroking, i. e., reflex vasoconstriction, the white line, in the disease epilepsy, is entitled "Idiopathic Epilepsy a Sympathicopathy" (7) (a word coined, by the way, to signify the diseased condition of sympathetic fibres found in that disease). In that communication it is shown that the white line has pathological significance; that its abnormalities are such in epilepsy that they present objective signs of the presence of the disease. Based upon the systematic investigation heretofore alluded to, it was found that in normal individuals the reaction time for the white line (i. e., the time it takes for the white line to appear after stroking) is equal on opposite sides of the body; e. g., if it takes eight seconds for the white line to appear on the right forearm, the reaction time, eight seconds, is the same for the left forearm; and if it takes twelve seconds for the white line to appear on the right side of the face, the reaction time, twelve seconds, is the same for the left side of the face. In epilepsy, it has been found that the reaction times on opposite sides of the body are, as a rule, unequal, unbalanced. Normally, it was found that there is a relative steadiness in the reaction times of the white line, while in epilepsy there is a daily variation in the reaction times, at one time the white line coming quicker on the left side of the body, and at another time coming quicker on the right side. Moreover in no condition is there evokable a white line more intense or longer lasting than in epilepsy.

Enough has been shown to demonstrate the fallacy of Wright's sweeping conclusion that the white line "is without pathological significance," which, by the way, could hardly be determined by the "investigation of one hundred healthy individuals"—the extent of the clinical investigation which he reports.

The relation of the white line to adrenal insufficiency, as well as to other disease conditions, can be best worked out by clinicians using a measured stimulus, the importance of which is, as explained above, fundamental.

The connection of the white line with the suprarenals by Sergent has always appeared to me felicitous. Sergent tested a patient having many symptoms of meningitis for Trousseau's sign, *la raie méningitique,* and instead of it, the white line appeared. A few days after, at autopsy of the case, complete cheesy destruction of the suprarenals and no meningeal involvement was found. Hence the connection expressed by the term *la ligne blanche surrenale.* I have also connected the white line with the suprarenals, and more definitely still, i. e., with the hormone made by the medullary tissue of the suprarenals, adrenin. Based upon experimentation and clinical observations previously reported (1, 8), I regard reflex vasoconstriction, the white line, as due to nerve stimuli evoked by sensory stimulation, going inwards along sensory paths, and, in nerve centres where the reflex occurs, reflected outwards over vasoconstrictor fibres to the contractile tissue of the vessels involved in the reflex, together with a sufficiency of adrenalin in the blood stream; that is, to be brief, the action of nerve stimuli plus adrenalin equals vasoconstriction. Without adrenalin in sufficiency in the blood stream, no vasoconstriction.

In his paper, Wright states there is no available proof that adrenin has any action on the capillaries, I would offer the following: Place a drop of adrenalin solution on the skin, and pierce the epiderm, wet with the drop, with a few pin pricks. Soon enough will be seen an intensely white spot due to the osmosis of the adrenalin under the epiderm. The intensely anemic area is due to vasoconstriction of the capillaries therein, as determined by Krogh's (9) investigations (which showed that "clinical hyperemia and anemia are due mainly to changes in the calibre of the capillaries and in the number of open capillaries").

Besides this experiment, a clinical observation is offered: I once witnessed the onset of marked pallor in a patient after the introduction into his vein of a small quantity of adrenalin (before this method of medication was recognized as dangerous with adrenalin). The patient was not emotional; he suffered no ill consequences save a momentary distressful sensation in the region of the heart. The anemia of the skin observed directly following the addition of adrenalin to the blood stream in this case, can be regarded as due to the action of adrenalin on the capillaries of the skin, since Krogh has shown that clinical anemia in a tissue is the expression of the contracted capillaries in that tissue.

Wright further states that Sergent regards the white line as an "arteriole" phenomenon. The eminent clinician repeatedly uses the term *le spasme capillaire* in reference to the white line, and nowhere in his book *Etudes sur L'Insuffisance Surrenale,* editions of 1914 and 1921, do I find any allusion to it as an arteriole phenomenon.

SUMMARY

1. The evidence that the normal reaction to stroking the skin (lightly) is brief lasting vasodilatation followed by longer lasting vasoconstriction remains unimpaired by Sampson Wright: failing to use the prescribed technic, he missed the phenomenon. The phenomenon was observed by M. Karasawa (Tokio), using an appropriate technic.

2. A measured stimulus must be used in evoking the vasomotor reflexes of the skin if they are to have scientific value, for the reason that the reflexes vary with the amount of stimulus used, and unless a measured stimulus be employed there is not identity of the phenomena under investigation.

3. The vasomotor reflexes of the skin, evoked with a measured stimulus, are of clinical value, since reflex vasodilatation (the first component of the normal reaction to stroking the skin) when evoked with a measured stimulus approximating two ounces, has been shown to have pathological significance if on the face it lasts longer than fourteen seconds; and the white line, reflex vasoconstriction (the second

component of the normal reaction) has been shown to have pathological significance and normal characteristics, some of which have been reported.

4. The abnormal vasomotor reflexes, showing recurring active diastole and systole of the capillaries, observed in four cases associated with nervous and irregular heart action, evidence that the capillaries, like the heart, are controlled by the vegetative nervous system.

5. The hormone adrenin is shown to have an action on the capillaries, a vasoconstrictive action.

The Present Status of Some of the More Common Dermatological Conditions

SAMUEL FELDMAN, M.D.
New York

In my college days, one of the professors characterized dermatology as follows: "Skin diseases are either eczema or not eczema and the treatment of both is the same." In the twenty odd years since, the subject of dermatology has made very rapid strides, keeping pace with the general progress of the age. Yet it is regarded very lightly by a large portion of the medical profession. Several of the more serious conditions have been incorporated in the textbooks on internal medicine on the plea that they are due to constitutional causes, among them being erysipelas, the purpura, herpes zoster, and several other dermatoses. As for the rest, it appears to be undignified on the part of our exalted profession to heed the suffering caused by such a vulgar discomfort as itching or the debility caused by marring of the personal appearance.

Aside from those mentioned above, there are numerous other dermatoses which originate from some disturbance within the system and are but symptoms of some general constitutional disease. Dermatological symptoms have the advantage of the visual picture which is more or less constant and it happens not infrequently that the dermatologist is the first to detect some obscure pathologic condition within the system. Early Addison's disease is a good example.

Even the reaction of the skin to external irritants is frequently dependent upon changes within the system. For example: chromophytosis can only be grafted upon a skin that has a special susceptibility for it. Blastomycosis is more common with patients who have high blood sugar. There is an individual susceptibility to poison ivy as well as to dermatitis from other causes. Microsporon ringworm heals spontaneously with the onset of puberty.

The popular belief that overfeeding with acids and condiments has something to do with causing certain dermatoses is clinically correct. It causes a disturbance in calcium metabolism and hyperacidity. The latter is known to be responsible for rosacea and herpes labialis. A diminution of the calcium content of the blood has been found to be nearly a constant accompaniment of a certain group of leg ulcers. Excellent results have been obtained from treating these patients with parathyroid, also from general and local applications of ultraviolet radiation which is known to have a definite and powerful effect on calcium metabolism.

Pruritus and eczema may accompany diabetes and nephritis or there may be evidence of a disturbance of kidney function without apparent kidney lesions. This will show itself in an increased chloride content and in nitrogen retention. The lesions in diabetes are most frequently located in the region of the genitals and the anus. They readily respond to diabetic diet and insulin medication. In some of the above mentioned diseases, as well as in urticaria, uricemia is found. This disturbance in purin metabolism appears to have a relation to the vegetative nervous system. They respond to atropin and cinchophen medication. Other cases of pruritus, eczema and urticaria are dependent upon vagotonus. They occur in patients with symptoms of the socalled vagotonic syndrome, such as asthma, hay fever, chronic conjunctivitis, and bradycardia. Hyperglycemia is usually present. The lesions as well as the hyperglycemia clear up under atropine.

Eczema occurring in the obese may depend upon either a disturbance in the thyroid or the pituitary. They can be differentiated by estimating the basal metabolism. The latter may be either increased or diminished in thyroid disease, but remains normal in cases with pituitary dysfunction. Many of these cases are due to protein anaphylaxis. Although there is no doubt that the latter is linked with the endocrine system, the manner in which it takes place is as yet not known. The instantaneous response of the exudative lesions, as well as attacks of asthma, to adrenalin medication speaks for its being due to endocrine disturbance.

The etiology of seborrheal dermatitis is still unknown. By some it is regarded as a bacterial infection. Several organisms have been blamed for its causation without any actual proof. On the other hand, in a majority of cases of that disease in children, a disturbance of fat digestion has been demonstrated and lately the same has been found in adults. There are other indications that this condition may be due to internal causes, namely—disturbances in

sugar and nitrogen metabolism. This is shown in the table below.

TABLE SHOWING RESULTS OF BLOOD CHEMISTRY IN SOME OF THE COMMON DERMATOSES[1]

Disease	No. of cases	Blood sugar in mgs.	Urea nitrogen in mgs.	Alkaline reserve in volumes of CO_2
Acute eczema	3	135	15.5	75
Chronic eczema	9	133	16	66
Chronic eczema	5	121	21.2	65.4
Sebor. dermatitis	8	146	16	67
Sebor. dermatitis	4	114	19.5	66.5
Simple acne	14	99	16.5	69
Pustular acne	17	145	15.2	65
Pruritus, urticaria	7	135	15.4	78
Psoriasis	8	130	19	67
Lupus erythemat	3	111	14	81
Scrophuloderma	9	110	18.5	53

[1]Figures indicate averages.

The blood was taken during the morning hours after a twelve hour fast from patients of the Lebanon and Bronx Hospital dispensaries and the laboratory work was done under the direction of Dr. S. Gitlow, director of the laboratory. The Ebstein and Folin methods were used for the sugar tests and the Van Slyke method for estimation of the alkaline reserve. Several interesting deductions can be made from the findings.

1. In some of the cases of eczema and seborrheal dermatitis there was a blood sugar content somewhat higher than that which is at present regarded as normal with a urea nitrogen within the normal limits, while in a smaller number of cases with a normal blood sugar there was a urea nitrogen content somewhat above the normal limits.

2. In simple acne the blood sugar content was within normal limits, while pustular acne yielded a sugar content well above the limits of normality, in agreement with the findings of many observers of a high sugar in all pustular skin diseases.

3. The alkaline reserve was within normal limits in practically all cases. This is in disagreement with the results obtained by Schwartz and Levine at Cornell, who found a lowered alkaline reserve in many cases of dermatitis and eczema. The discrepancy may perhaps be partly accounted for by the fact that the above mentioned workers had the blood taken in the afternoon and not after a period of rest and fasting.

From this brief résumé of the possible etiological causes of the above named group of very common dermatological conditions, one can readily see the difficulty in handling them. The subject of the interaction of the endocrines is not well understood. The response to the protein test is only about twenty per cent. certain. There are numerous other cases of eczema which are due to external irritants. For example, that occurring on the necks of women from wearing fur collars, and on the hands and arms from the Japanese lacquer on mah jong sets. There is a large group of trade eczemas, among them being the dermatoses occurring in dentists from the use of novocaine, in cement workers, in washerwomen, and in bakers and grocers from handling flour and sugar. To top this there is a group of very common dermatoses due to epidermophyton infection which is not readily differentiated from the eczema of other causes and in which the fungus is not readily demonstrated. Furthermore, skin inflammation which has existed for a long time may persist even after the cause has been eliminated. The process of finding and eliminating the cause is time consuming and often quite costly. The patient is interested primarily in being relieved from his suffering and is not willing to wait. It is fortunate, however, that we have certain means at our command that will at least temporarily cure eczema, although in many cases it is not possible to assure the patient that there will not be any recurrences.

Recently attempts have been made to desensitize the patient against protein anaphylaxis in general, without actually finding the particular protein at fault. This is done in one of two ways: either by giving him a small quantity of peptone half an hour before each meal or by injecting some foreign protein. The latter is administered in the form of sterile milk or in the form of a specially prepared protein, which has an advantage over milk in that it causes less severe reactions. The results so far obtained are quite promising.

Aside from finding and removing the cause, in acute eczema the management of the case is directed at first towards soothing the irritation and itching. This is best accomplished by the nightly bran bath, by soothing applications, and even wet dressings. The ultraviolet radiations from the quartz mercury lamp have a very beneficial influence in these cases. It should be applied to the point of a mild erythema every second day until the attack is under control. In cases of generalized acute eczema there are often several patches that refuse to yield and become chronic. They should subsequently be treated as such.

In chronic eczema when the disease is generalized we resort to stimulating medication such as salicylic acid and tar. The ultraviolet rays, however, will help clear up most of the cases. If the disease is more or less localized, x rays yield extremely gratifying results. One quarter of an erythema dose applied once a week will clear up the condition in from one to four applications.

The drugs commonly used in seborrheal dermatitis are resorcin and ammoniated mercury. Ultraviolet radiations from the air cooled quartz mercury lamp, however, act almost as a specific and will clear up an attack with but few exposures. This is equally true of the same condition in children.

In the limited scope of this paper it is not possible to touch even lightly upon all dermatological conditions due to internal causes. Two very common dermatoses must, however, be briefly mentioned. Psoriasis has been attributed to the thymus and is being treated with either extract of the gland or the stimulating doses of x rays applied to it. A small number of cures have been reported. Acne occurs at the onset of puberty. There are characteristic hair changes in this condition. In the male, the beard is sparse, while in the female there is usually hirsuties. There is a diminished sex appetite. All these symptoms point to the origin of the disease in a dysfunction of the gonads. My attention has recently been called to a number of patients who exhibited acne after pregnancy. These women asserted that they had a perfectly clear skin before that time. Others have noticed that acne, which had existed for a long time, disappeared with the occurrence of pregnancy. This further strengthens the possibility of its being of endocrine origin. Yet the results obtained from endocrine treatment are far from being brilliant.

One enthusiast of this method of treatment reports fifty per cent. cures. I doubt whether there are many that share this enthusiasm. On the other hand, x rays of medium hardness in one quarter doses applied once a week for a period of about ten weeks will result in a permanent cure in most of the cases.

SUMMARY AND CONCLUSIONS

Undoubtedly much has been accomplished toward putting dermatology on a rational basis by finding the cause of many conditions which, until quite recently, has been entirely obscure. Yet much obscurity still exists and it will require a great amount of effort on the part of the present and perhaps the future generation to clarify the field to such an extent as to make it possible to treat these conditions solely by eliminating the cause.

On the other hand, the results obtained from the application of physical therapy are so pronounced that no dermatologist can at this time afford to overlook this agent.

The x ray apparatus and the quartz mercury lamp are the most important agents in the armamentarium of the dermatologist of today.

1955 Grand Concourse.

Psoriasis Diffusa With Extensive Arthritis

A. A. RADCLIFFE, M.D.
Waukegan, Ill.

At the request of a visiting nurse, the following case of psoriasis diffusa, with extensive arthritis, was taken as a study, treated at my expense, hoping to be able to give some relief, for the patient's condition was pitiable.

Case.—The patient, a widow aged thirty-seven, a university graduate, formerly a school teacher, had been in good health until the age of twenty-six. She gave the following history:

In December, 1913, a dozen or more isolated spots of psoriasis appeared on chest and thighs, starting as a pimple and enlarging to an area half an inch in diameter, and lasting four or five weeks.

In December, 1914, a painful neuritis on the inner side of the left thigh confined her to her bed. An eruption of psoriasis started, reaching its height in a month, covering the scalp and much of the body; none on hands and feet. It was not very red and began to subside in March, 1915. The hair on her head grew again and was thick and dark brown in color. Arthritis had stiffened her knees.

Through the summer of 1915 there was no eruption, but the patient experienced some difficulty in ascending stairs from stiffened knees. She taught school from September to June, 1916.

In August, 1916, the eruption appeared on the scalp, the chest, and the arms, all being above the waist line, and it subsided in March, 1917. The patient's tonsils were removed in February, 1917. Arthritis had extended. In February, 1917, adhesions in knees, ankles and wrists were broken by force, and were broken again in September. There was no eruption throughout the summer of 1917.

In the fall of 1917 the eruption appeared, covering the scalp and much of the body nearly to the knees. This faded in July, 1918. In May, 1918, she was at a noted medical clinic where her eruption was pronounced the worst care of psoriasis they had seen.

Every fall since then the eruption has appeared, covering much of her body above the knees, subsiding in the spring or early summer, a few spots an inch and a half in diameter remaining. The hair of the scalp fell out, but came back quite thick.

The eruption of 1923 started early in the fall, fading by May, 1924. The patient's limbs were stiff and painful and she had not been able to feed herself since January. In April she menstruated, the first time for three years, also in June and first of July.

In July, 1924, her eruption started to spread. She was seen the last week in September. She had not walked for six years, nor had been able to turn on either side for nearly three years. Her joints had been very sore and painful for several months.

Every joint of her limbs was ankylosed. The distal ends of the first phalanx of the middle finger of both hands were dislocated towards the palm of hand. The fingers of the right hand were curved into the palm of the hand; the fingers of the left hand were straight. The finger nails were long, thick, yellow and curled to a point. On two fingers of the right hand a nail had grown backward and curled under itself. Both arms were so sensitive that the least movement of the pillow upon which they lay gave agonizing pain. The backs of both hands were edematous, pitting deeply on pressure. The knees were ankylosed in partial flexion, the tibias dislocated backward scarcely resting against the femurs, the hip joints so stiffened as to permit of only a half sitting posture. The ankles were greatly enlarged, and toenails thick, lumpy and of a yellowish color.

The eruption covered nearly her whole body, a larger area than ever before, starting earlier, the scales larger and thicker, the eruption a darker red, only her face entirely free from it. Her scalp, the back of the neck, extending into the ears, were completely covered. Her arms from shoulders to elbows were nearly covered and from elbows to finger tips completely covered; palms of hands only reddened. From above the breasts down to the soles of the feet, anterior and posterior, her body was completely covered, excepting the anterior third of the soles of the feet, where the skin was normal. All parts of the eruption seemed infiltrated. On the back of the neck, scalp, lower portion of abdomen, inner side of both thighs and both heels the eruption was purplish, the knees and forearms nearly so, the other parts a darker red than arterial blood.

Thick yellowish and dirty white scales, some over one inch by two inches, could be removed. They caused irritation, the visiting nurse removing daily

nearly a double handful of scales, a drop or two of blood showing where scales had not entirely loosened. The skin beneath the scales was shiny, looking as though it would bleed if touched. On the lower border of the right breast there was a warty excrescence four inches long, one inch wide, elevated half an inch, blackish color, dry, fissured like rough bark. There was a smaller one on each thigh at the gluteal fold. These came in the spring of 1924.

The patient could not be moved so that the back could be examined, as her limbs were too sensitive. Pulling the draw sheet from under her often brought tears to her eyes from the pain, the sheet coming out thick with large scales and a few drops of blood. Another sheet sprinkled with powdered boric acid and starch was pulled under her. The starch getting pasty, talcum proved better.

Not able to scratch herself, and too sore to permit others to do so, the itching was sometimes unbearable. Vomiting occurred frequently; some days she was not able to retain food, and at other times she had a good appetite and no distress after eating. Occasionally she was feverish in the evenings and sweat profusely, especially on those parts which rested on the bed, and on the inner side of thighs.

In previous attacks arsenic by mouth and muscular injection and the usual external applications had not shown benefit, and the patient would not consent to another trial of these remedies. Arsenic would not have corrected the systemic condition which seemed the probable cause of her attacks. External applications can be likened to mopping up a wet floor under a leaking roof. Psoriasis and pityriasis must be the expression of a systemic condition. Empirical methods are as shooting at game without taking sight, a hit would be a wonder, not likely to occur.

The hydrated oxide of calcium was given, as experience has convinced me it is far better than any of its salts, which have to be decomposed for the calcium to form organic compounds. And by improving digestion by the use of enzymes the calcium acted more quickly.

Parathyroid was given as it has been credited with "controlling the metabolism of calcium, preventing, removing, or destroying toxins in the blood." Reports have been made, that calcium by mouth does not prove beneficial until conjoined with parathyroid.

A half ounce of full strength aqua calcis was prescribed four times a day. She feared it would disturb her stomach, but at a vomiting spell the visiting nurse persuaded her to try it, a teaspoonful diluted every ten or fifteen minutes until vomiting and nausea stopped. It gave such quick relief she had the nurse telephone me her thanks for it. The calcium was then to be taken, half an ounce, diluted, four times a day. Her mouth secretions being strongly acid four grains of sodium hydroxide were added to half a pint of lime water. This was given for two or three days, then only the calcium was taken.

Improvement showed within three days, and in less than a week the edema of her hands had disappeared, and there was a decided fading of the eruption. In less than two weeks the purplish parts had faded to a lighter color than other parts had been, the whole eruption being much lighter color, the scales thinner and whiter, spots of clearing skin showing. There was no vomiting or night sweats. This much could be attributed to the calcium. In a few days enzymes were added to the treatment, to be taken at meals, the elixir of pepsin with one eighth of a diastase to increase the amylolytic action of the enzymes, as starches seem difficult for some to digest.

In about three weeks the back of her neck and scalp were normal in color, free from scales, the hair on her head scattering, almost bald on top. Large patches of clear skin showed everywhere, her breasts were nearly cleared. Small scales were falling, or were easily brushed off like a powder. Parathyroid extract, one tenth grain, three times a day, was added to the treatment.

In about five weeks the whole body was cleared of the eruption, excepting three small pale red spots, with no scales, just above the left iliac crest, and two similar spots on the back of the right shoulder. These spots have remained for at least three years.

In about six weeks the pain and soreness of her joints had left and by shoulder movement she wrote her name, the first time since early in January, 1924, she had been able to move either arm.

The soreness of her joints subsiding, this seems partly, if not wholly attributable to the enzymes acting by improving digestion, the food being more perfectly converted into substances that could be metabolized. There have been reports of benefit in arthritis from the use of yeast, which acts as enzymes aiding digestion, as in my experience from such enzymes as used in this case of psoriasis. In another case I should begin with the full treatment.

By the middle of December the patient's face showed plumpness, a clear skin with quite florid cheeks, a regaining of her former good looks, a great contrast to the sallowness of September. Her forearms were flexible to nearly a right angle. She menstruated in December the first time since July. Now, the middle of January, 1925, her body is clear of eruption, the spots above hip scarcely showing, the hair on her head is much thicker. The mouth secretions are alkaline, not beyond normal.

The history of this case, as in all cases of psoriasis, has been that the eruptions were at their height during fall and winter months, clearing towards spring, leaving a few small patches, returning the next fall. At no previous attack has her eruption cleared or faded as in this attack. This is the first December since 1915 that she has been free of an eruption covering much of her body. There are hopes that by enabling her to go through January and February free of eruption, which she has not done for the past eight years, the vicious cycle may be broken, at least a partial cure effected, preventing a return of a diffused form next fall. To accomplish this the treatment should be strictly carried out with the greatest care in order to demonstrate what it has given evidence of doing.

This case does not prove that the treatment will be effectual in all cases of psoriasis, though it seems to have been in this case, yet it is worthy of further trial which I hope others will test, for I may never have another opportunity to try it.

Radiotherapy in Dermatology

OSCAR L. LEVIN, M.D.
New York

For the treatment of surface lesions it is desirable to have a flat applicator containing the radium salt spread out so that the amount of radium per square centimetre of surface is the strength of the applicator. The full strength applicator contains five milligrams of radium to the square centimetre. However, for general dermatological use the half strength applicator containing ten milligrams of radium element is a most convenient device. With such an applicator it is easy to obtain the proper screening with either aluminum or brass and to measure the varied lengths of exposure for removing cosmetic blemishes.

There is no standard method of measuring the dose for the various cutaneous manifestations. The unit of measure is the millicurie hour which is equal to one millicurie of emanation applied for one hour or sixty millicuries for one minute. It is customary to express the strength of the radium used in millicuries of emanation or milligrams of radium element and the length of exposure depends entirely on the strength of the applicator, the distance from the skin, the density of the tissue treated, the extent of the surface covered and the character of the radiation.

The rays tend to stimulate or inhibit or destroy the growing property of cells and their reproductory capacities, especially in the case of embryological, gland and neoplastic or inflammatory cells. Cells differ in their susceptibility to radiation. The undifferentiated or embryonal cell is more susceptible, whereas the highly specialized type of cell is more resistant. Cells which are growing are of course more reactive than cells which are resting. Cells containing large amounts of chromatin, likewise, are more easily destroyed. Often the degree of malignancy of a tumor may be determined from a histological study of these factors before any dosage can be estimated. The endothelial lining of bloodvessels is very sensitive to radium and as a result, tumors having a great blood supply react more readily to radium than those with a scanty flow of blood. Tumors which have small amounts of connective tissue like epitheliomata and sarcomata are more radiosensitive than fibromata and organized keloids.

In dermatological practice it is noticed that lesions with acute inflammatory infiltrates of round cells are the least resistant and most readily reactive, as in simple dermatitis and eczema. Second to these in sensitivity to radiotherapy are the chronic inflammatory lesions which contain the connective tissue cells. Among the simple inflammatory lesions responsive to the radium rays are chronic eczema, psoriasis, neurodermatitis, patches of persistent seborrheic eczema, lichen planus and the prurigos. Tissues containing giant or plasma or epitheloid cells come third in their resistance to radiation; and, neoplastic cells, epithelial and glandular, are the most difficult to irradiate of any of the pathological cells. The normal tissue cells being in a resting state are more resistant than any of the pathological cells.

In inflammatory infiltrations like chronic eczema, lichen planus, psoriasis, radium has afforded a great deal of relief. In treating those lesions which are covered with crusts and scales it is first advisable to remove them by means of oily preparations and soothing bland wet dressings. The dose of radium should not be more than one or two milligram hours and a rubber filter is necessary. Treatment may be carried out by using one half strength glazed applicators screened with one tenth of a millimetre of brass or lead and weekly exposures of one half hour may be administered.

Granulomata which have yielded to radiotherapy are the leucemids, leucemic infiltrations, Hodgkin's disease and mycosis fungoides, and of course, while the rays cure the localized lesions they do not influence the general course of the particular condition.

Radium has also been valuable in infectious conditions like ringworm and favus of the scalp, tuberculous infections like lupus vulgaris, lupus erythematosus, tuberculosis verrucosa cutis and erythema induratum. Destructive doses, using one half strength applicators with one tenth of a millimetre screen of lead, applied for one or two hours at intervals of one week may be employed for tuberculous lesions.

Radium is indicated in neuroses of the skin like localized pruritis where the best method is by means of unscreened applicators, in three to five minute exposures repeated at intervals of one week. One third strength plaques may be used, screened with one tenth of a millimetre of aluminum for not more than fifty or sixty minutes in toto.

Among the benign tumors affected by radium are nævi and birthmarks. Small port wine birthmarks may be removed with one half strength applicators with light screening of either rubber or aluminum but the flat port wine marks do not yield readily to treatment. The cosmetic results obtained in the treatment of vascular nævi, however, are little short of magical. For the small lesions, the surface applicators of radium element are best and most convenient. One quarter strength applicators, unscreened, may be applied closely to the skin for a period of two hours at a time, at intervals of one week, or it may be applied for five hour periods if screened with one tenth millimetre of lead. However, for the vascular nævi which cover large areas, the best results are obtained by means of radium seeds because a greater area can thus be covered at one time. With the emanations the danger of exposing the normal skin to the rays is also greatly reduced.

Cavernous angiomata are readily affected by the gamma and beta rays and a full strength applicator may be used with a one tenth millimetre screen of lead. The dose of course depends upon the thickness of the vascular tissue but an exposure of no more than an hour or two should be given at one time. The deeper angiomata of course require the hardest, most penetrating rays, the gamma rays, and the best method is either by means of radium seeds or full strength applicators with brass filters which eliminate the hard beta rays. To avoid superficial irritations by the secondary rays which the gamma rays produce, the distance may be measured inasmuch as the

intensity of the radiation is in inverse proportion to the distance (although not exactly according to the inverse square law). The radium needles which may be conveniently embedded in such lesions may be left in the soft tissue for two hours or more without any destructive effect on the surrounding normal tissues.

Lymphangiomata which have been difficult to deal with in the past have yielded readily to radium.

Multiple benign cystic epitheliomata, situated as they usually are, on the face, and being difficult to treat, have been a great problem to the dermatologist inasmuch as before the use of radium it was almost impossible to obtain a good cosmetic effect. Often the cicatrices which formed were far more unsightly than the lesions themselves had been. In the treatment of these growths radium has acted miraculously, removing the lesions with no scarring.

The use of radium is especially indicated in small keloids and is to be preferred to the x rays. It is important in treating keloids to diagnose the lesion correctly and then to undertake treatment as early as possible. The extreme base of the lesion must be reached and treatment discontinued when no more palpable thickness is left. Best for small keloids is the one quarter to one half strength plaque with a screen of one tenth of a millimetre of brass, exposed for one or two hours. The result obtained is a smooth atrophic surface, soft and elastic and if proper filtering is used, the possible development of telangiectasias is avoided.

Painful plantar warts and callosities are easily and quickly removed with radium. Usually a one half strength plaque applied for from one half to two hours is sufficient to cause involution.

Radium has been a most valuable agent in precancerous affections like senile keratoses, Paget's disease, Darier's precancerous dyskeratosis, leucoplakia, xeroderma pigmentosum, and x ray keratoses. These potentially malignant conditions yield very readily to small doses of the element. The use of a one quarter strength applicator, unscreened for about one half hour to two hours, or screened with one tenth millimetre of lead for three to four hours is recommended. In the treatment of keratoses resulting from radiodermatitis, they should be considered as any other keratoses in nature, even though their origin was the röntgen rays. It is a most peculiar phenomenon that the soft beta rays of radium used in small doses will cure the keratoses produced by excessive doses of x rays.

Radiotherapy has proved of value in the malignant tumors of the skin like basal and prickle celled epitheliomata, lymphosarcoma and melanosarcoma. The dose varies with the character of the lesion, its clinical type and microscopic structure; and in these cases it is most important for the procedure to include simultaneous treatment of the anatomically related lymph nodes, with either radium or the x rays. In dealing with large, deeply infiltrated and ulcerated growths the gamma rays are most effective. It is often advisable in squamous celled epitheliomata to give an intensive dose of about two hundred millicuries, screened with two millimetres of brass at a distance of three centimetres for thirty hours in periods of ten or more hours each. This treatment in smaller doses might be repeated after about six weeks to two months if the disease persists and there are no signs of irritation by radium. In the treatment of basal celled epitheliomata radium is very important. As a matter of fact, this type of epithelioma is most amenable to the rays, and treatment of less intensity than that recommended for squamous celled epitheliomata is effective. Good results are often obtained by removing the tumor with endothermy and following the operation with radiotherapy.

In passing, it might be mentioned that radium is very effective for permanent depilation, but its use in hypertrichosis is not recommended by the writer, inasmuch as the development of atrophy and telangiectasias is inevitable, and rarely is it advisable to produce atrophy of the skin.

In the use of radium, the untoward clinical effects of the element upon the normal skin must be carefully watched for and guarded against. An inflammatory reaction known as radiodermatitis may come from a single intensive dose or may be the cumulative effect of several small doses, and it may be accompanied by subjective symptoms like burning, stinging, itching and possibly edema and swelling of the glands in the area treated. There may be some desquamation and pigmentation and the depilation of the area treated may be temporary or permanent. A more intense burn from radium may lead to superficial ulceration, beginning with a moist, exudative, eroded surface and leading to complete destruction of the epidermis. This type of ulceration sometimes will heal spontaneously, but when the necrosis caused by radium involves the true skin the ulcer may remain for years or persist indefinitely. A third degree burn from radium may give rise to dry, hard, necrosed masses like dry gangrene which eventually sloughs and gives rise to a deeply punched out ulcer, accompanied by excruciating pain.

Other unpleasant effects which the physicians must try to ward off are telangiectasias, cutaneous atrophy which appears in the form of fine wrinkling, pigmentation or depigmentation, the reduction of sebaceous activity and the development of keratoses and carcinomata.

In view of these possible disastrous effects of radiotherapy, it is of utmost importance that great care and skill be exercised in the application of the chemical to the human body. It is of utmost importance, likewise, that the physician be thoroughly acquainted with the microscopic nature of the particular lesions to be treated and the chemical nature of the element. He must also learn to recognize the beginning of the untoward symptoms and regulate his doses accordingly.

In conclusion, there is nothing more to say than that radium seems to be the method of choice in the treatment of numerous skin affections, particularly in those which involve a thickening of the tissue as in cases of granulomas, vascular nævi, verrucous growths, keloids, and a tendency to malignancy as in epitheliomata and sarcomata. However, much harm can be done if the radium is used promiscuously and blindly. The physician must be able to interpret the lesions in terms of their particular structure and pathology, and be acquainted with the methods of regulating doses carefully, for while radium is one of the most powerful therapeutic agents, it is also one of the most dangerous.

Historical Medicine

Remarks on the Hygiene of the Ancient Greeks

CHARLES GREENE CUMSTON, M. D.
Geneva, Switzerland

Gymnastic exercises of every description were unquestionably carried to the highest perfection among the ancient Greeks. Their love of physical exercise influenced their art, health, and genius, and they understood it far better than we do today. Contrary to presentday teachings, their school children did not at once specialize in a given exercise or sport. Every child was obliged to learn at least five, viz., running, jumping, throwing the disc and spear, and wrestling. The sounds of the flute regulated the movements, while the master superintended all, ready to correct any breach of the rules.

Since dislocations and fractures frequently occurred in the palestra, the professors of gymnastics were surgeons as well, or at least were bonesetters. They even went further, because in 500 B. C. they had already applied gymnastics to the treatment of disease. Precursor of the Swedish, a master of a gymnasium, one Herodicus, himself of weakly constitution, corrected his feeble health by regular exercise and following his example arthritic and frail subjects derived health from these means.

The Greeks well knew the untoward results accruing from the abuse of sports. Hippocrates mentions them and Galen further developed the question in his exhortation for the study of the arts. However, at the time Galen lived, the Romans had given up sports in favor of professionals and it is curious to compare the brute types of athletes appearing in the Roman circus with the harmonious types of Greek statuary.

The Greeks developed the hygiene of alimentation; it was part of the treatment of disease and many books of the Hippocratic collection are devoted to this subject. That compared with our times the Greeks were more sober in the use of alcohol is not to be doubted, but the people loved their wine and the mental excitement derived therefrom they deified in the person of Bacchus accompanied by Silenus and satyrs. During their orgiastic festivals, wine gave prophetic inspiration to the bacchantes. There were inveterate drunkards as well, because Asclepiades attributes congestion and sclerosis of the liver to *oenophilia,* while Hippocrates has described delirium tremens.

The ancient Greek physicians condemned the use of alcohol and advised an early walk. In cases of fever they ordered an abundant intake of fluids and allowed no solid food. In Plutarch's time mixed or highly spiced foods were condemned by the medical profession. All these rules form the basis of the alimentary hygiene of today, but the goddess Hygeia who presides over them does not receive the worship to which she is entitled.

When patients who had come to consult the priests had passed through the propyleums of Asclepieion at Epindaurus, they came face to face with an inscription in large letters: Absolute Cleanliness.

The organization of life in the open in ancient Greece is an interesting study. Under the *stoai* (porticos) which were built in the meanest village, the Greeks not only walked and amused themselves, but also kept school and meeted out justice. With the same interest in hygiene, the planting of trees was a constant anxiety of urban architects. Of this we have the testimony of contemporary writers who dwell upon the profusion of trees and plants at Athens, especially platanes, the olive trees of Megara and the public places of Chalcis transformed into forests. Certain public monuments were even hidden by this abundant foliage.

Even today, with our housekeeping and other material difficulties of living, the intellectual classes have envisaged the possibility of creating garden cities in the suburbs of large cities, reserved for artists, etc., even as the Athenian philosophers and poets were installed over an area of some two square miles lying between Ilissos and the Cephesis. Students came to dwell among them and were lodged in humble thatched huts of wood, and there alternated bodily exercises with those of the mind, in the sovereign calm of the Attic countryside. A vegetarian diet was highly *a la mode* then just as it is at the present time, honey enjoying a great reputation as a valuable food.

The physicians of those distant days prided themselves upon their superior intellectual culture which even Plato was compelled to acknowledge. Not content with palpating painful shins or searching for the causes of distressing symptoms, they philosophized with their patients, and in reality, is not this the principal secret of successful physicians today, and which in numberless cases is more effective than pills and compressed tablets?

The study of the texts and paintings on vases reveal the fact that the ancient Greeks were well skilled in hydrotherapy and knew full well the virtues of sea bathing quite as much as those of the shower bath. The municipal authorities organized public baths. Sunbaths and hot air baths were much in vogue. Thermal sources had their clientele and the rule in every well ordered house was to offer a bath to guests in order to relieve them of the dust of travel, and likewise to dispose them for the pleasures of the table.

Every dwelling, even modest ones, had a bath house containing one or several bathing tubs, situated without, close by the terrace. In the homeric times, baths were taken in *asaminths,* large shallow marble or silver vessels, while later on vast tubs, supported on pedestals, were used. Partial bathing, especially of the feet, was common in the homeric period. This duty, as well as the care of the bath in general for visitors, was incumbent upon the servants, and upon special occasions Penelope confided this care to her old nurse as a mark of respect to some sage

and elderly foreigner. The servant poured water upon the visitor from a jar over the head and shoulders, but the elegant ladies of those days, probably anxious to protect the undulation of their hair, put on a cap when they took a bath. There were also bathing pools where swimming could be practised.

The public baths were supplied with masseurs, and a kind of soap (*rhymmata*) as well as perfumes, could be obtained. The ancient Greeks built sanatoria and building around them was prohibited. And this leads to the question of the architectural principles of the times which reveal a constant care for proper ventilation and favorable sites for building. The roofs were flat and the occupants of the house often sat or slept on them. The windows were left open during sleep.

Moreover, the Ediles kept the city clean. Athens had her drains and sewers, although these were not novel, since Nineveh long before had superb ones. Strabo is wrong when he accuses the Greeks of having neglected the laying down of paved streets, and not to have constructed sewers and aqueducts. A very original point in the construction of the great sewer of Athens is referred to by Mr. Guillaume in his article entitled Cloaca, in the *Dictionnaire des Antiquités Grecques et Romaines.* Its end terminated in a reservoir from which brick conduits carried off the contents, distributing them in open country outside the city.

Let us now briefly consider the theories of epidemics held by the Greeks, and here Prof. E. Jeanselme's opinion should be quoted. "To affirm that all the means employed by modern hygiene were known to the Greeks and that the progress of science has merely developed the principles conceived by Greek minds is an exaggerated assertion." This remark of Jeanselme unquestionably is true, but at the same time one should endeavor to ascertain exactly what we really do owe to the Greeks. When one speaks of Hellenic culture it is treated in dithyrambic praise, but only generalities are discussed.

The first agent of contagion devised by man was the devil. It was because the demon entered into the body and possessed it that caused man to fall ill. Treatment consisted of exorcism. Later on, when mankind conceived the idea of gods, it attributed disease—as well as all other ills—to wicked gods. And when the gods disappeared from his mentality, man believed that disease was caused by the one just God, who thus punished human beings for their errors.

But with the advent of Hippocrates all this changed. In paragraph 24, of *Air, Water, and Places,* it is stated that "Every disease has a natural cause, and cannot be produced without a natural cause." This sums up the opinion of the learned of the time. But the people believed that epilepsy and convulsions were caused by divine power, hence the name *morbus sacer* given to them. In his treatise on the *Sacred Disease,* Hippocrates proves that this is likewise due to natural causes and that the supernatural should be eliminated from medicine.

This was an enormous step forward, but of the natural causes of disease and epidemic maladies in particular, the Greeks were ignorant, and the centuries after them were likewise ignorant. The theory accepted by physicians was that of miasmata and at length their truth was proved by the immortal Pasteur by scientific demonstration. The theory of miasmatic contagion consequently was not devoid of a basis, because the ancients well knew that the atmosphere exhaled by decomposing matter, such as sewerage, was fatal, and that certain soils, such as the Dogs' Grotto near Naples, give off lethal or deleterious vapors which were finally shown to be carbonic acid. Therefore, their theory is not entirely erroneous, but they made the mistake of generalizing it, so that it at length became erroneous from a too general application.

Maimonides on Sexual Laws in the Old Testament

LOUIS J. BRAGMAN, M.D.
Syracuse, N. Y.

In chapter forty-nine of *The Guide of the Perplexed,* that repository of philosophical wisdom by Maimonides, are found several references to the laws of forbidden sexual intercourse as proscribed in the Old Testament. Although the notations of the great physician and reformer of the twelfth century in this regard are somewhat concise they are none the less filled with a highly moral significance, and are clear and decisive in their import.

"The Law," Maimonides says, "seeks in all its parts to inculcate the lesson that we ought to limit sexual intercourse altogether, and hold it in contempt, and only desire it very rarely." He is here, no doubt, speaking against the prevailing gross tendencies of the period, for he insists that the object of the bans was not merely to diminish carnal relationship, but "to teach that such enjoyment is in itself not the final cause."

There is a brief mention made of the evils of homosexuality and bestiality. "The prohibition of pederasty and carnal intercourse with beasts is very clear." He then refers the reader to Leviticus XVIII, 22, which specifies: "Thou shalt not lie with mankind as with womankind. It is an abomination." Further (*ibid* 23), "Thou shalt not lie with any beast to defile thyself therewith; neither shall any woman stand before a beast, to lie down thereto; it is perversion."

"If in the natural way," the *Guide* states, "the act is too base to be performed except when needed, how much more base is it if performed in an unnatural way and only for the sake of pleasure?"

Of incest he remarks: "License between the root and the branch, between a man and his mother or her daughter is outrageous." Leviticus XVIII goes into much detail on this score, enumerating the various possibilities of this relationship, and admonishing vigorously against them: "None of you shall approach to any that is near of kin to him, to uncover their nakedness." The members of the household being constantly in association with the head of the family would easily listen and yield to him. He could thus without difficulty procure them.

"It makes no difference," he adds, "whether the male element is the root or the branch." And also "we must not indulge in any sensual enjoyment whatever with persons included in the above prohibition." We must not even look at them if we intend to derive such pleasure from them. This is obviously a very stringent rule to follow.

Advice against onanism is offered in a practical way. "We must not engage our thoughts with acts of cohabitation, or irritate the organ of generation. When we find ourselves in a state of irritation we must turn our minds to other thoughts." He quotes from the sages of old who warned: "My son, if that monster meets you, drag it in the house of study. It will melt if it is of iron, it will break in pieces if it is of stone."

"See how properly the term monster is used," Maimonides comments, "for that irritation is indeed like a monster."

How similar is the counsel of the physician Rondibilis (in Osler's *Principles and Practice of Medicine,* 8th edition, page 278) who told Panurge that carnal concupiscence could be cooled and quelled by hard work of body and mind.

Another way of avoiding the stirring up of sexual ideas, we are told, is to refrain from watching birds and beasts in the act of copulation. This is one reason, Maimonides believed, for the law against cross-breeding of animals (Leviticus XIX, 19).

He interprets the inauguration of the practice of circumcision as a means not only of solidifying a race by giving it a mark of identification, but of "limiting sexual intercourse, weakening the organ of generation, and moderating man." It is performed, then, not as a "complement to a deficient physical creation, but for perfecting man's moral shortcomings."

This reasoning, however, is not consistent with Genesis I, 22, which commands the race to "be fruitful and multiply." One readily discerns in these commentaries of the Dark Ages a Puritanical undercurrent which is far removed from the liberal interpretations of today.

Contributors to the Science of Medicine

William Budd

William Budd, practitioner of medicine, careful student and logical thinker in the science of epidemiology, was born in September, 1811, in North Tawton, a town on the borders of the beautiful Dartmoor in Devonshire, England. He was the fifth son of Samuel Budd, being one of nine brothers, seven of whom entered the medical profession and became leading practitioners. The family was one of great talent. Five sons were graduated from Cambridge. Four of these were fellows of their respective colleges, and all were wranglers. Four of Dr. William Budd's nephews likewise became fellows of colleges in the same university. Both Dr. William Budd and his older brother, Dr. George Budd, the author of the great work on *Diseases of the Liver,* were fellows of the Royal Society.

With his eight brothers, William Budd was educated in the home of his father, himself a surgeon of no mean ability. In 1827, when he was sixteen years of age, he went to Paris. There he studied for four years under Louis Andral, Cruvelhier and Broussais in the College de France and the Ecole de Médecine, and, under the tuition of Broussais, first became acquainted with the intestinal lesions of typhoid fever. While in Paris he contracted typhoid, and the leeching and starvation, which was the accepted treatment of the disease at that time, was carried to such a point that he was unable to pursue his studies for several years. In spite of this, he valued bleeding very highly in the early part of his career. Returning from Paris, he continued his medical studies in London and Edinburgh, and subsequently became a pupil of Sir Thomas Watson at the Middlesex Hospital. This is the "Sir T. Watson, Bart.," to whom Budd dedicated his *opus magnum, Typhoid Fever, Its Nature, Mode of Spreading and Prevention,* "in grateful remembrance of many encouraging words."

In 1838 Budd took the M.D. degree from the University of Edinburgh and after graduation he served for a short time as physician to the seamen's hospital ship *Dreadnaught* at Greenwich, but was compelled to resign his post because of an attack of typhus fever of which he almost died. In 1839, during his convalescence, he resided with his brother, Dr. Richard Budd, of Barnstaple, and prepared an essay on *Fever,* in competition for the Warneford prize of £50. He failed to receive the award, however, because the judges, of whom Sir John Forbes was umpire, were of the opinion that the ideas enunciated in his essay were "too novel and startling."

In 1839 Budd returned to North Tawton and entered into practice with his father, and here began those intensive studies which were to be the basis of his work on *Typhoid Fever, Its Nature, Mode of Spreading and Prevention,* published over thirty years later. In this environment Budd was able to study the disease in all its manifestations and to

correlate the going and the coming of those who were affected with it. He realized fully the opportunities which the situation offered, and wrote many years later:

"Where the question at issue is that of the propagation of disease by human intercourse, rural districts, where the population is thin, and the lines of intercourse are few and always easily traced, offer opportunities for its settlement which are not to be met with in the crowded haunts of large towns."

As a result of his observations at this time he came to the conclusion that the fever was essentially a contagious or selfpropagated disease.

Not only did Budd decide that the disease was contagious, but he came to the conclusion that it was of a specific nature. And in 1873 he clearly prophesied the existence of the bacillus which was not discovered until some seven or eight years later. He said:

"It is humilitating to think that issues such as these should be contingent on the powers of a creature so low in the scale of being that the mildew which springs up on decaying wood must be considered high in comparison."

He also came to the conclusion, from the foregoing, that typhoid fever not only propagates itself, but that it propagates no other kind of fever.

In the course of his studies—studies which he never relinquished until forced by the hand of age—he early came to the very logical conclusion that the pollution of water supplies was the great factor in typhoid transmission. In fact, Budd recognized all the media of transmission now known, with the possible exception of flies. In his work on typhoid he says:

"One mode of communication has attracted little attention, which it is important, nevertheless, not to overlook; I speak of the tainted hands of those who wait on the sick. Among the poor, and in ways that will suggest themselves, and need not be more particularly described, there is reason to believe that this mode often has a large share in spreading the disease through the family circle. Passing from the hand to other things under contingencies that are not only very conceivable, but are sure now and then to occur, the contagion thus arising may sometimes have a much wider scope. I possess evidence which renders it in the highest degree probable that milk and butter, especially, may become infected in this way."

As preventive measures, Budd at all times laid strong emphasis on the disinfection of the discharges of the sick, the isolation of all typhoid patients, the careful and frequent washing of the hands of the attendant, and the boiling of the drinking water. Truly, as he says, "These are golden rules; where they are neglected the fever may become a deadly scourge; where they are strictly carried out, it seldom spreads beyond the person first attacked."

Budd's lasting contribution to the science of epidemiology may best be summed up in the summary of his book on typhoid fever. Other researches he made, to be sure, but many of these were contingent on his typhoid studies; studies which brought us nearer to the absolute prevention and eradication of this disease than the work of any other observer, either before or since his time. It, therefore, seems fitting that the words which closed the *opus magnum* of his life, words which in reality closed the book of his scientific labors, should be the final chapter in this story of that pioneer epidemiologist, William Budd. The labors of a lifetime, and the ambitions of his career, are summed up in the following propositions:

"1. That typhoid fever is in its essence, a contagious or selfpropagating fever, and is a member of the great natural family of contagious fevers, of which smallpox may be taken to be the type.

"2. That the living body of the infected man is the soil in which the specific poison, which is the cause of the fever, breeds and multiplies.

"3. That the reproduction of this poison in the infected body and the disturbance attaching to it constitute the fever.

"4. That this reproduction is the same in kind as that of which we have, in smallpox, ocular demonstration.

"5. That the disease of the intestine, which is its distinctive anatomical mark, is the specific eruption of the fever, and bears the same pathological relation to it which the smallpox eruption bears to smallpox.

"6. That, as might have been anticipated from this view, the contagious matter by which the fever is propagated is cast off, chiefly, in the discharge from the diseased intestine.

"7. That, as a necessary result, sewers and the cloacæ which, under existing sanitary arrangements, are the common receptacles of these discharges, are also the principal instruments in the transmission of the contagion; and, consequently, that in many instances the infected sewer, and not the infected man, appears as if it were the primary source of the specific poison.

"8. That once cast off by the intestine, this poison may communicate the fever to other persons in two principal ways—either by contaminating the drinking water, or by infecting the air.

"9. That, as an inevitable consequence of the impalpable minuteness of the contagious unit, and the many invisible and untraceable ways in which it is transmitted, cases must be constantly occurring, exactly as in the other contagious fevers, whose linear descent cannot be followed, and which spring up, therefore, under the semblance of spontaneous origin.

"10. That the occurrence of such cases obviously constitutes no proof whatever that this fever ever does arise spontaneously.

"11. That the exceeding speciality of the conditions attaching to the reproduction of the specific poison in the living body itself, as well as the facts relating to the geographical distribution, past and present, of this and the other contagious fevers, constitute evidence as strong as such evidence can ever be that none of these fevers originate spontaneously, but are propagated solely by the law of continuous succession.

"And lastly—to crown the whole induction by a practical test—that by destroying the infective power of the intestinal discharges, by strong chemicals or otherwise, the spread of the fever may be entirely prevented, and that by repeating this process in every fresh case as it arises the disease may in time be finally extinguished.

"And let no one suppose that this is a matter in which he has no personal interest. The duty itself we may evade, but we can never be sure of evading the penalties of its neglect. This disease not seldom attacks the rich, but it thrives most among the poor. But by reason of our common humanity we are all, whether rich or poor, more nearly related here than we are apt to think. The members of the great human family are, in fact, bound together by a thousand secret ties, of whose existence the world in general little dreams.

"And he that was never yet connected with his poorer neighbor, by deeds of charity or love, may one day find, when it is too late, that he is connected with him by a bond which may bring them both, at once, to a common grave."

The Study of the Pulse.—Dr. William Shainline Middleton, in his article on "A Biographical History of Physical Diagnosis," appearing in *The Annals of Medical History,* for December, 1924, says: "The study of the pulse was neglected by physicians until Herophilus of Alexandria (335-280 B.C.). No mention of the pulse is found in the works of Hippocrates. Galen, however, established a system of medicine on the minutiæ of pulse variations.

"The accurate timing of the pulse may be traced to Galileo Galilei (1564-1642), although Sanctorius is incorrectly credited with this contribution to medical science. Born in Pisa of a noble though impecunious Florentime family, Galileo was gifted with brilliant intellect, mechanical ingenuity and assiduous application. His father, a prominent mathematician and musician, endeavored to guide his son's training to more remunerative fields. After a preparatory course in Latin and Greek at the monastery of Valombrosa, Galileo entered upon the study of medicine in his eighteenth year under the renowned Andrea Cesalpino (1524-1603) at the University of Pisa. The immortal observation of a bronze lamp swinging in the duomo at Pisa was but one of a series of mechanical discoveries which insidiously drew his master mind from the field of medicine into astronomy and experimental philosophy.

"However, this fundamental discovery of the isochronism of the pendulum was first timed by the young medical student with his own pulse and fifty years later he remarked of his astronomical clock, 'My clock will not vary so much as the beat of a pulse. Galileo applied the term, 'pulsilogon' to his invention. Medicine did not immediately avail itself of the obvious advantages of the pulsilogon. Another astronomer, Herman Kepler, wrote in the year 1618:

" 'In a healthy man, robust and of full age, in one of melancholic complexion, or in a feeble man, generally for each second there is a pulsation of the artery, with no discrimination between systole and diastole; thus there should be in one minute sixty pulsations, but this slowness is rare, commonly 70 may be counted, and in the fullblooded and in women 80, four to each three seconds. Briefly, in one hour 4,000, more or less.'

"Sydenham did not mention the pulse rate and Harvey (1578-1657) spoke of it but once. Morgagni (1682-1771) recorded the first example of heart block (Stokes-Adams syndrome) with a pulse of 22 in 'the sixtieth of an hour.' In 1707 Sir John Floyer dedicated 'The Physician's Pulse Watch' to Queen Anne with the patronizing air of a Steele, 'for without health we should have no relish even for the extraordinary blessings of your reign.' The watch described ran for sixty seconds. The text contains some very important observations, but the innovation was greeted with derision by the profession at large. S. Weir Mitchell aptly characterized the state of medicine in the eighteenth century: 'It is observation gone minutely made; a whole Lilliput of symptoms; an exasperating waste of human intelligence.'

"From the extreme overzealousness of Heberden (1710-1801) in pulse study, one passes to the complete ignoring of the pulse rate by Corvisart. To Louis and the Dublin school must go the credit of the routine pulse determination at a period two hundred years removed from the medically neglected discovery of Galileo."

Bark as a Drug.—William Macmichael in his book, *The Gold Headed Cane,* gives an interesting account of the discovery and early use of bark as medicine.

A number of cinchona trees, he writes, were thrown into a pool in Peru and lay there till the water became so bitter that everyone refused to drink it. One of the neighboring inhabitants was suddenly seized one day with a violent paroxysm of fever, and, finding no other water to quench his thirst, was forced to drink from the bitter pool, "by which he was perfectly cured." He afterwards told some of his friends who were ill with fever and they made use of the same remedy, which again proved successful. "But it was not only the casual experience of an uncivilized people which discovered this valuable remedy, but the first prejudices against its use, which were very strong, were counteracted by the influence of a religious sect (the Jesuits), totally unconnected with the practice of medicine; and physicians were ultimately taught how to use it with effect by a man who was vilified both at home and abroad as an ignorant empiric."

Sydenham, when speaking of the use of bark as a medicine, is very contradictory in his statements and seems to have been afraid to employ it efficiently, and it was not till Louis XIV. bought the secret of the method of giving it that the real virtues of the drug were properly felt and universally acknowledged. Talbor was the name of the man from whom Louis bought the secret, and while his cure of the King was in progress, Madame de Sévigné describes in a letter most amusingly the anxiety over it of every one at court, and the fury of M. D'Aquin, first physician to the King. Talbor was knighted but died the year after he had triumphantly exhibited his skill in the curing of Louis. The King then ordered the secret to be published for the benefit of mankind.

The same monarch introduced ipecac into general practice, having induced Helvetius to use it largely for the cure of dysentery in 1679.

Editorial Articles

EDUCATION BY DEPARTMENTS OF HEALTH

It is interesting these days to scan the weekly or monthly bulletin of the departments of health in different cities and to make comparisons, not only of these with each other, but of the general nature of all of them with health reports of a decade or two ago.

The very existence of the bulletin of a health department is worth considering. If we are right, such a piece of literature has not existed long, though there have, of course, been annual health reports for some time back, and the bulletins as they now exist grew out of this. Some of these documents have not, in fact, progressed greatly beyond the stage of the annual statistical returns issued now in weekly or monthly installments. One of such reports which we open is half made up of vital statistics of births and deaths. Now vital statistics are well enough in their way, but in the weekly way, except in epidemics, they signify almost nothing, and even a monthly rate means little to the average, even professional, reader. It certainly does not make anybody any healthier. Another city does better in offering its socalled normal rate besides its current rate of sickness and death. The Health Officer of this city is certainly frank, for among other normal rates is that for smallpox. In the first mentioned bulletin there is also a list of health supply stations, some remarks on the typhoid oyster situation and on what one division of the health department is doing. The bulletin is excellent in its way, but it is evidently intended primarily for the members of the department and, to some extent, the physicians of the city. Probably its circulation is chiefly limited to these. The layman would certainly find it of little interest and no benefit.

A bulletin of another city contains, in the same number of pages as the preceding, effects of influenza on the general death rate, new milk regulations, the health play, what should a school child's lunch consist of? school rooms should be carefully ventilated, queries and answers, food suggestions, crossword health puzzle and measles. Perhaps half of these articles appeal to, and are written for, the laity.

A bulletin from still another city is devoted almost entirely to the subject of dress. It is intended altogether for the laity, except one page devoted to a quarterly report on typhoid fever. This bulletin may be said to represent the latest type of public health work, the education of the layman in personal and community hygiene. The first bulletin stands for the work of the department of a quarter century ago, while the second belongs to a transition period. It is interesting to note that in the bulletin which still lays emphasis on sanitation, the print is the smallest and there are no pictures; while in the third bulletin, devoted to informing the general public on matters of health, the type is much larger and there are attractive illustrations.

Now in the departments of health of all three of these cities much the same routine of laboratory work, sanitary inspection, isolation for communicable disease, etc., is going on, and one department is as efficient as the others, but the bulletin which represents the most up to date service reflects the present condition of affairs so far as real progress is concerned. Until further advance is made in the prevention of communicable disease and other laboratory discoveries in connection with illness, the chief business of the department of public health, aside from routine left over from the last century, is the educating of the laity to an appreciation and practice of what is now known concerning the laws of community and personal health. Someone should do this, and why not the department of health? The physician can do his important share by word of mouth, but the health authorities have a better opportunity for broadcasting through the printed page.

THE NATURE AND TREATMENT OF DISEASE

Empiricism in medicine still flourishes and it continues to flourish because empirical treatment is found effective frequently, although the originating cause of disease may be so extremely obscure as to be practically unknown. As a matter of fact the discovery of the causal organism of a disease does not appear to assist greatly in its successful treatment. If it did so assist why has not pulmonary tuberculosis been almost extinguished seeing that Koch's discovery took place more than forty years ago. Moreover, it is pointed out editorially in the *Lancet*, January 3, 1925, that in spite of Laveran's discovery of the malarial parasite in 1880, the value of cinchona bark as an empirical remedy was known and utilized more than two hundred years before.

There are indeed many examples of the efficacy of empirical treatment, a treatment which clinical experience has demonstrated on innumerable occasions to be effective. Little is known of the exact manner in which many drugs do their work, although

they have or appear to have a distinct action in curtailing the inroads of a disease or in modifying its virulence.

Disease is largely a question of whether the defenses of the body are in a strong enough condition to resist successfully the attacks of the enemy. If the body is healthy such attacks come to naught and if the defensive powers are at a low ebb they are successful in proportion to the diminished strength of the defenses. Also, the old belief that inherited diathesis has something, perhaps much, to do with the progress of certain chronic diseases seems again to be coming to the front. Inherited predisposition may be a factor of considerable importance and it may be the case that the sins of the fathers are visited upon the children more often than is generally supposed. Sir James Mackenzie has for long both preached and practised that symptoms are too frequently treated and that insufficient care is exercised in finding out the originating causes of a malady and that minor ailments are considered too casually by both doctor and patient, with the result that these ailments become serious and sometimes lapse into chronic conditions. The rheumatic diseases, socalled, exemplify these views in the most striking way.

In order to cope with disease effectively earnest and early cooperation between the medical man and the patient is absolutely necessary and the situation as regards cancer affords sinister testimony to the truth of this statement. Cancer in all its forms is amenable to treatment in its early stages, and a main reason why it is so deadly is because, as a rule, it is not diagnosed early enough for treatment to be of much avail. Education of the public is required not only as to the beginnings of cancer but of most of the chronic diseases, and of the necessity for consulting a physician before it is too late.

As far as therapeutic treatment is concerned, the view that drugs exert a directly inhibitive or destructive effect on the invading organism is waning. With respect to the action of quinine on the malarial parasite, its rapid disappearance, as shown by experimental evidence, almost negatives the theory that it exerts destructive effects on the plasmodia. Rather it must be believed that it directly or indirectly stimulates the defensive mechanism of the body to organize to destroy the malarial organism or impair its potency. And so it is probably with the majority of human maladies.

Progress is being made in the direction of more precise knowledge of the nature of disease, and it is likely that advance will be comparatively rapid while effective treatment will be equally rapid if not more rapid, as treatment is not wholly dependent on the knowledge of the cause of disease. It may be predicted that this year long strides will be made towards the goal which all medical men are endeavoring to reach, namely, the discovery of the nature of disease and the ideal treatment.

DECREASE IN MALARIA IN THE CANAL ZONE

During the first ten years of American occupation of the Canal Zone, the average rate of malaria among employees on the Panama Canal was 293 in one thousand workers; for the ten year period, just ended—the second of American occupation—the rate was twenty-eight in one thousand, and for the year 1923 the rate was nineteen in one thousand. A summary of the report of the health department is given in a recent number of the *Panama Canal Record*. This report states that the greater part of present day malaria among employees occurs in colored laborers, including the transient, the occasionally employed, and those whose work requires residence or exposure in unsanitated areas. Dr. Henry R. Carter, assistant surgeon general of the United States Public Health Service, who recently inspected the work in the Zone, stated that at the time of his service there, in reconstruction days, about 1904-1909, a rate of two per cent. of employees a week—more than a hundred per cent. a year—was considered a fair standard of malaria control for the locality, and that the present rate of less than two per cent. a year was then considered an utter impossibility.

The report goes on to describe the intensive work recently undertaken by the Division of Sanitation, much of which is not apparent to the casual eye, as was the case when efforts were confined largely to residential sections. About five years ago the Health Department intensified its program of malaria prevention and elimination by permanent filling or draining of nearby mosquito breeding areas, thus making unnecessary the oft repeated work of cleaning out ditches, oiling puddles, cutting grass, inspecting premises, etc. "The drain, buried in the earth and unnoticed by the passerby, often took the place of the oil or larvacide man, and the black smear along the roadside. . . . At the same time, similar methods of permanent control by filling and draining were adopted in other more distant sections, with the result that extensive breeding areas which were formerly entirely neglected have now been completely eliminated. Within a general radius of one mile from the borders of the Zone towns and terminal cities, no mosquito breeding whatever is tolerated. Where danger appears to threaten from areas as far as two miles distant (and even further in case of the large swamps on the Atlantic coast) drainage is

being instituted to control the development of mosquitoes."

The sanitary forces are being gradually reduced in numbers, a step which has become possible through the change from temporary to permanent measures of control. The cost of sanitation is being correspondingly reduced.

The Division of Sanitation is now chiefly concerned, aside from its efforts against malaria, with preventing the introduction of bubonic plague from South or Central American seaports. The report says: "As a result of painstaking work by the sanitary forces and of splendid cooperative efforts made by other departments or divisions of the Panama Canal, the terminal cities and towns are approaching a condition which would render the spread of plague most unlikely, even if a human case or an infected rat were introduced from some vessel. Many thousands of infected rats are caught each year and examined in the health department laboratory to determine if the germ of the plague is present. Ratproofing of structures is steadily progressing. No case of human plague and no infected rat has been known to exist in the Zone since 1905, in which year two colored laborers contracted the disease at La Boca and died. A thorough antirodent campaign in the infected area wiped out the focus of infection. With the Canal now in operation, it is important to remember that the development of a single case of plague locally, or the finding of a plague infected rat, would cost the Canal and commerce an almost unlimited sum of money in quarantine restrictions and efforts at eradication."

BLOOD, URIC ACID, GOUT AND SKIN AFFECTIONS

While there is no belief nowadays that diseases are directly inherited, the belief in the inheritance of a diathesis or predisposition to a disease appears to be rather gaining than losing ground. Of all these diatheses that of uric acid seems to be the one with regard to the heredity of which medical opinion is the most confirmed. As for gout, the evidence in support of its being a hereditary disease is very strong, that is, the predisposition to it and the disease may lie latent until it is evoked into activity by other causes. The connection between gout and uric acid is by no means so obvious as might be supposed. After it had been demonstrated that the blood of gouty persons contained uric acid in abnormal quantities, the hypothesis that uric acid played an essential part in its causation seemed proved. Further investigations have shown that the problem is not so simple as was thought at first. In cases of gout it is true that there is usually a considerable increase in the amount of uric acid in the blood, but uric acid may also be increased in other diseases distinct from gout, in severe cases of nephritis, for instance.

Therefore, the increase in the uric acid in the blood is not pathognomonic of gout, although it is extremely suggestive of it. The most striking evidence in favor of uric acid being the chief factor in the development of gout is that diet in which purin bodies predominate will delay the excretion of uric acid in a gouty patient and bring on an attack and that careful dieting and measures to eliminate uric acid from the system will relieve an attack. The uric acid predisposition or diathesis provides the soil and gout merely signifies that the goutiness or latent condition has been aroused to activity. That there is a very intimate relationship between the presence in the body of an excess of uric acid and gout and goutiness cannot be denied although the exact relationship is not quite obvious.

With regard to blood uric acid in skin diseases, some remarkably interesting experimental investigations have been made recently by Dr. Jay Frank Schamberg, director, and Mr. Herman Brown, chemist of the Research Institute of Cutaneous Medicine, Philadelphia. Dr. Schamberg and Mr. Brown presented a paper before the American Dermatological Association on the blood uric acid in diseases of the skin with particular reference to eczema and pruritus. This article was published in the *American Journal of Dermatology and Syphilology,* December, 1923.

The authors pointed out that there was a tendency on the part of American writers on dermatology to pay little or no attention to the relationship of gout and eczema, which had always been emphasized by French dermatologists and, to some extent, by skin specialists in Great Britain, especially by Pilbury Fox. Although there is no unanimity as to what constitutes the maximum normal for uric acid in the blood, Schamberg and Brown hold that it is about three and seven tenths mg. per hundred c. c. of blood; estimated by this standard forty-four per cent. of their 161 cases of eczema and fifty per cent. of ten cases of pruritus showed an excess of uric acid in the blood. Other skin diseases showed a lower percentage. These findings are instructive and are in keeping with those of the leading French dermatologists.

This paper suggests another point which is worthy of notice, namely, that American medical literature on gout is scanty. French physicians are the most voluminous writers on the subject, while among British writers Garrod and Llewellyn have made clear certain obscure features. Gout is more rare in this country than in Europe. Also, the type of the disease has altered considerably everywhere, and the acute, explosive, excruciatingly painful form

is seldom met with nowadays. In some countries what is known as rheumatic gout is common and goutiness or susceptibility to the disease is prevalent in this country, if not so often seen as in certain parts of Europe.

Goutiness manifests itself in many and various ways which, as it is due to insufficient or perverted metabolism leading either to the formation of material which is foreign to a healthy condition or to the inadequate discharge of normal excretion and elimination, cannot be wondered at. There is a something foreign in the blood, which, in its endeavors to find an outlet, may attack any organ or tissue and the form assumed will depend upon the organ or tissue selected or which refers the best opportunity for escape of the alien body. The poison or foreign something may attack the neighborhood of joints bringing about a chronic gouty arthritis; it may take refuge in the sheaths of nerves causing a neuritis. As said before, it may cause skin diseases. It may make the air passages the sphere of its noxious activity and cause pharyngitis, laryngitis, bronchitis, or asthma. It may turn its attention to the stomach and induce dyspepsia. It may choose the brain and give rise to irritability, sleepiness, and sluggishness. It may bring on a cystitis, pyelitis, and perhaps even a urethritis. No part of the body can claim freedom from invasion of the uric acid poison. It has been suggested, and quite plausibly, that the underlying cause of these manifestations, largely due to an excess of uric acid in the system, is an imbalance of the endocrine glands. It may be further suggested that in many instances this imbalance is owing to chronic intestinal toxemia brought about by prolonged gastrointestinal disorders, the chief of which is constipation.

The sequence of events may be somewhat as follows: Obstinate constipation followed by intestinal stasis and ending in alimentary toxemia, one or other of the endocrine glands has its functions impeded and there is a lack of the usual harmonious team work between these glands which results in an upset of the system, disordered metabolism, uric acid forms in abnormal quantities in those predisposed and any of the gouty or socalled rheumatic manifestations are likely to ensue. If in a gouty patient there is delay in the excretion of uric acid one of two things has occurred, the diminution in the uric acid output may be due to an increased destruction in the body or to its retention by the kidneys. As there is no evidence of increased destruction in the body, the conclusion is reasonable that it is retained by the kidneys. The most clearly indicated method of treatment is to prevent an attack of gout or allied affections from coming to a crisis by the promotion of free diuresis. If uric acid has collected in the kidneys in such amounts as to hamper their proper working, the obvious method of effective treatment is to promote free diuresis. In all diseases practically adequate elimination and excretion are essential to complete recovery. In gouty conditions and the like in which the urinary tract is involved, this method of treatment is especially necessary. Careful diet is the first prerequisite, but some means of relieving the kidneys of the foreign substance or substances which clog them are also called for.

REFORM IN RONTGENOLOGY

The field of röntgenology is a fertile one for the charlatan. Steps have already been taken by various communities—New York city among them—to meet this evil, but much more is to be done than the passage of laws requiring the licensing of röntgen laboratories.

The American Journal of Röntgenology and Radium Therapy has recently made a plea through its editorial columns for the inauguration of a crusade for reform in the field of röntgenology similar to that undertaken by the American Medical Association in the field of drugs. The journal purposes to have a "column" in which information and suggestions along these lines will appear. A request is made for advertisements, circulars and general information from all legitimate sources about practitioners of röntgenology who should not be practising.

Such a step toward a needed reform should receive the cooperation of all selfrespecting practitioners of medicine.

AMERICAN HEART ASSOCIATION ANNUAL MEETING

The first annual meeting of the American Heart Association was held at the New York Academy of Medicine, Monday afternoon, February 2, 1925. Dr. Lewis A. Conner, the president, reviewed briefly the progress of the development of the association and commented on the need for such an organization and the widespread interest which its formation had developed. Dr. Haven Emerson, chairman of the committee on membership, described the methods employed to reach all parts of the United States and Canada; regional agents covering one or more states have been appointed and already thirty-seven states are represented in the membership of the association. The following program for the coming year was adopted:

1. Maintenance of a central office. As a headquarters through which all the work of the association may be organized and directed. This office is already established but the personnel must be increased to keep pace with the demands which are increasing daily.

2. Organization and membership. One of the first and most important steps in the development of the organization of the association is that of securing contacts with all parts of the United States and Canada. This is to be accomplished by appointing regional representatives and obtaining a large and widely distributed membership.

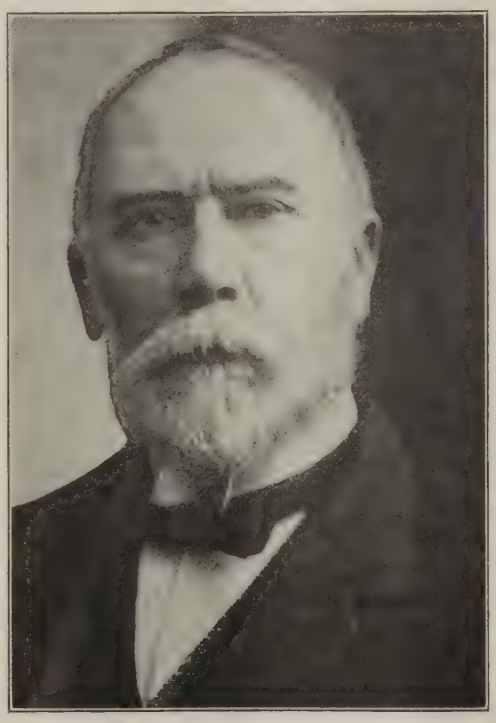
3. Field work. One or more workers with a knowledge of the most recent and approved methods for the prevention of heart disease and the organized care of cardiac patients, who shall be available to be sent to different sections of the country to encourage the establishment of new centres, demonstrate the methods found to be effective, and aid in solving local problems as they arise.

Obituary.

SIR JAMES MACKENZIE, M.D., F.R.S., F.R.C.P.

St. Andrews, Scotland

Pioneers of medical science may be counted almost on the fingers, and in the death of Sir James Mackenzie one of these pioneers has just passed away. The life of the man who revolutionized the study and treatment of heart disease is a romance of medicine. A graduate of medicine of Edinburgh University he went to Burnley, a busy, smoky, cotton spinning Lancashire town, as a general practitioner in 1879, and found like most men of commanding talent find and acknowledge, that they are profoundly ignorant in many respects. But unlike the majority of general practitioners who are content to follow tradition and routine, Mackenzie possessed the inquisitiveness of the searcher after truth and the perseverance and grit to pursue investigations under immense difficulties. He felt impelled to dissipate some of the ignorance which beset him and directed his attention to unravelling some of the problems of symptoms. The average general practitioner in an industrial district has quite enough to do to cope with the ordinary work, but Mackenzie made his general practice the field of persistent and painstaking research. As a matter of fact he planned one of the most stupendous tasks of research work ever thought of which involved the collecting and tabulating of thousands of individual records and consequently an amount of labor impossible to the ordinary man. Of course, Mackenzie was not an ordinary man, rather a genius who solved problems that had baffled the most skillful clinicians for ages, and his surpassing achievements in the realms of cardiology were even more fully acknowledged in other countries than in his own.



SIR JAMES MACKENZIE

For twenty years his labors continued without lagging and at the end of that time he had accumulated such a mass of knowledge and had broken so much new ground, that when he published his famous book with it all in, he fairly took the medical world by storm. His book was quickly published in most of the European languages and indeed he had established a new school of cardiology. He was more than fifty years old when he came to London but his reputation was made and he came into consulting practice under favorable auspices. Lord Knutsford, chairman of the London Hospital, that large institution situated in the poorest district of the metropolis, was his staunch friend and through his influence Mackenzie was given wards in the London Hospital. He had also become physician to the Mount Vernon Hospital for Diseases of the Chest and the work done there and at the London Hospital corroborated the accuracy of Mackenzie's early deductions while at the same time it afforded him scope to widen his field of knowledge. By this time, as said before, a school had arisen with the former Burnley general practitioner as its founder.

The outbreak of war interrupted his studies, although by this time he had formed a large and lucrative consulting practice. However, his aim was to trace disease to its secret lairs rather than to treat it and as he was convinced that study and treatment would be at a standstill until the general practitioner became a research worker, because the general practitioner alone sees the earliest signs of disease, he set himself, at the height of his fame to resume the work begun in Lancashire and in collaboration with general practitioners to probe the secrets of the origin of disease. For this purpose he betook himself to St. Andrews "the grey o'd toon by the sea" in his native Scotland where he gathered round him the general practitioners of the place to work with him. They eagerly assented and the greatest medical scientific figure of the day, the man whom his fellow men of all lands had delighted to honor, foregathered with family doctors in the endeavor to lift the veil which obscured the mystery of disease yet a little higher. While it is too early to pass any definite opinion on the value of the work done in St. Andrews, those who were most closely in touch affirm that very considerable progress was made.

Mackenzie's view of treatment was of a preventive nature, that complaints if treated in time, would be prevented from developing into grave disease and his object in St. Andrews was to learn more of the beginnings of disease. Of Sir James Mackenzie's contribution to the world's knowledge of the heart no terms of eulogy can be too high. He blazed the trail and is said to have acknowledged that although he had made a few discoveries in connection with the heart the trail was only blazed. After all, it is the pioneer who bears the heat and burden of the day who is of the greatest account and Mackenzie's name will be linked with the great

names of medicine as the most famous cardiologist in that he pointed the way.

It is one of the ironies of fate that the man who was an acknowledged authority on heart disease should fall a victim to angina pectoris. Sir James was seventy-one years of age. He was knighted in 1915 and elected F.R.S. the following year. He was LL.D. of Aberdeen and Edinburgh Universities and a few weeks ago was awarded the Charles Mickle Fellowship Prize of the University of Toronto as a recognition of his labors for medicine and medical science.

He was Oliver Sharpley lecturer to the Royal College of Physicians and Schorstein lecturer at the London Hospital in 1911 and Gibson Memorial lecturer at Edinburgh in 1914. His publications included *Study of the Pulse, Diseases of the Heart, Symptoms and Their Interpretations,* and *Principles of the Diagnosis and Treatment of Heart Affections.* In illustration of the habit of mind of Sir James Mackenzie, some years ago the writer called on him to ask for a paper from him for an American medical journal. When he had made his request Dr. Mackenzie, as he was then, said, "I never write, Sir, unless I have something to say," and when he was interrogated as to whether he had nothing to say at the time, he answered "Nothing." He did not rush into print for the sake of writing but only wrote when he felt that what he had to say should be made public for the sake of humanity and in the cause of science. Sir James Mackenzie returned from his work at St. Andrews only a few months ago, and died in London on January 26, 1925.

JOHN HUNTER, M.D.

SYDNEY, AUSTRALIA

The sudden death of Dr. John Hunter from enteric fever which occurred at the London University College Hospital on December 10th, comes as a tragedy to modern scientific medicine. He delivered the John B. Murphy lecture in surgery at the New York meeting of the Clinical Congress of the American College of Surgeons on October 20th.

Although Dr. Hunter was only twenty-seven years of age, he had made for himself a notable place both as a teacher and a scientific investigator, particularly in anatomy. Perhaps his most notable work, and that for which he is best known in this country, was that in connection with Dr. N. D. Royle on spastic paralysis, which created unusual interest among surgeons, orthopedists and neurologists of the world.

John Hunter was born in 1898 at Bendigo, State of Victoria. Throughout his infancy he was threatened with being a cripple, but his mother left no stone unturned in her efforts to obtain the best corrective treatment for him, and he was finally saved by surgery. Thus at the early age of seven, he became interested in this branch of medicine. The expenses of his treatment had completely depleted the family income and savings, so that most of his boyhood and youth were of necessity devoted almost exclusively to supporting himself and his mother; but, as one of his biographers has said, "instead of becoming depressed by his early struggles, he seemed to get added zest for the joy of life from the feeling that he had surmounted difficulties; he was a most delightful and joyful companion and it was amazing that, in spite of the adulation showered upon him by students and the public, he always remained the most modest and unassuming of men."

In the course of his early years, he had a bad attack of pneumonia which induced his mother to take him to live with an aunt in New South Wales, Australia, where he spent the rest of his life, and where he came under the influence of Prof. J. T. Wilson, now of Cambridge, who supervised his scientific and social interests and studies. He was graduated from the University of Sydney in 1920 with the highest honors in his class and the university medal. Upon his graduation he was appointed senior demonstrator of anatomy, acting as resident of the Royal Prince Alfred Hospital during vacations. When, a few months later, Wilson was appointed to the chair of anatomy at Cambridge, he saw to it that Hunter was put in the way of succeeding him, and within a short time the young man, at the age of twenty-three, was made professor of anatomy. Before he assumed his duties, it was considered advisable for him to tour Europe and America for observation and study, and it was while making this tour that he contracted the infection which caused his death.

As has been said, probably Hunter's most notable work, and his most recent, was with spastic paralysis, but before he left Australia, he had cleared up many of the difficulties in the interpretation of ovarian pregnancy, in the real significance of the occurrence of Neanderthaloid characters in Australians, and in analyzing the complicated factors of spinal shock following transverse section of the spinal cord. While he was in the United States and Canada, he gave demonstrations and lectures in many of the medical centres of both countries. He then went to England to expound the outcome of his work and was taken ill the week he was to demonstrate. His death occurred after a brief illness.

One of his colleagues has written: "To those who have come under the spell of his genius and learned the truth of the teaching for which he has given his life, it must remain ever a duty and privilege to expound his work in the effort to convince others of its truth and to extend its applications by experiment and clinical application." Prof. G. Elliot Smith has said, that, had Hunter been spared, he would have been perhaps "the biggest figure in scientific medicine of the present generation."

News Items.

Harvey Society Lecture.—Dr. Oscar M. Schloss, professor of pediatrics, Cornell University Medical School, will deliver the seventh Harvey Society Lecture at the New York Academy of Medicine, on Saturday evening, March 21, 1925. His subject will be The Intestinal Absorption of Antigenic Protein in Infancy.

Neurological Research Committee.—The Commissioner of Health of New York has called together a committee to study the epidemiological, diagnostic, clinical, and therapeutic data in relation to diseases of the nervous system. Dr. Charles L. Dana was elected chairman, and the other members are: Dr. W. W. Browning, Dr. Dever S. Byard, Mr. E. H. Lewinski-Corwin, Dr. Louis I. Harris, Dr. Howard Mason, Dr. William H. Park, Dr. Frederick Tilney, Dr. E. G. Zabriskie, and exofficio, Dr. Frank J. Monaghan, health commissioner.

Dr. Madill Honored.—The St. Lawrence County Society of New York held its annual dinner at the Hotel Astor, February 19th, with Dr. Grant C. Madill, former president of the Medical Society of the State of New York, as guest of honor.

Teaching of Stomatology.—The New York Polyclinic Medical School and Hospital has established a section of stomatology, in connection with its department of gastroenterology. Alfred J. Asgis, D.D.S. has been appointed clinical professor of stomatology.

The Smoke Nuisance.—Dr. Herman S. Peck, deputy health commissioner of Brooklyn, is taking active interest in the campaign for the suppression of smoke. Section 211 of the sanitary code of New York City is directed against unnecessary smoke.

Clinic for Speech Defects.—A clinic for speech defects has been established by the department of public speaking of New York University, Washington Square. Serious cases will receive the cooperation of the New York University Medical College and Flower Hospital.

Postgraduate Courses.—The medical school of the University of California is arranging courses in general medicine and surgery, and numerous specialities, under the direction of Dr. Eugene S. Kilgore of San Francisco, to be given June 15 to July 11, at San Francisco.

Noble Wiley Jones Lectures.—Dr. Anton J. Carlson, professor of physiology of the University of Chicago, will deliver the Noble Wiley Jones lectures at Portland, Oregon, March 23d to 26th. His subjects will be Gastric Secretion in Health and Disease, Problem of the Endocrines (two lectures), Motor Disturbances of the Alimentary Canal, and Problem of the Liver.

Chandler Medal.—Dr. Edward Calvin Kendall, of the University of Minnesota, and head of the Mayo Foundation for Medical Research, has received the Chandler medal for distinguished achievement in science. His lecture was on Influence of the Thyroid Gland on Oxidation of the Animal Organization, and was delivered February 12 at Havemeyer Hall, Columbia University.

New Public Health Association.—The following are the officers of the newly organized Pennsylvania Public Health Association: Dr. Charles H. Miner, Harrisburg, president; Dr. Wilmer Krusen, Philadelphia, and Dr. Carey J. Vaux, Pittsburgh, vice-presidents; Dr. William C. Miller, Harrisburg, secretary and treasurer. A public conference will be held in June at Mont Alto.

Meeting on Syphilis.—The Rehabilitation Institute and General Hospital Clinical Society will hold a meeting March 9th at nine p. m., at the hospital, 328 West Forty-second Street, to be devoted to syphilis in its clinical manifestations. Dr. Herman Goodman will present moving pictures and lantern slides of spirocheta pallida (in motion), cutaneous lesions, and visceral changes. Physicians are invited to attend.

Ella Sachs Plotz Foundation.—Applications for grants from the Ella Sachs Plotz Foundation for the year 1925-1926 should be received by Dr. Francis W. Peabody, secretary, Boston City Hospital, Boston, before May 15th. However, consideration will be still given to applications up to September 15th, if the funds are not all used. Of thirty-two applications, eight grants were made, four of them on the general subject of chronic nephritis.

American Ward in London Hospital.—An effort is being made to raise an endowment fund of $60,000, for twelve beds in the George Washington Ward of the Royal Free Hospital of London, a maternity ward named in recognition of the help given the hospital by the American Women's Club of London during and since the war. Dr. May Thorne, an English physician, and one of the governors of the hospital, is in this country in the interests of the fund, and delivered a lecture at Bellevue.

Study of Thromboangiitis Obliterans.—A committee has been organized for the study and treatment of Thromboangiitis obliterans, with Dr. Reginald Sayre as chairman and Dr. Benjamin Jablons as secretary. The membership of this committee is as follows: Dr. Fred H. Albee, Robert F. Barber, Harlow Brooks, Leo Buerger, G. A. Friedman, A. L. Garbat, Charles Goodman, I. W. Held, Harry E. Isaacs, Maximilian Lewson, Willy Meyer, Marcus Neustaedter, A. I. Ringer, DeWitt Stetten, Gregory Stragnell, Benjamin T. Tilton, Walter Timme, Walter Truslow and Dr. Henry Keller.

Cancer Clinics.—The health department of Columbus, Ohio, has arranged six free cancer clinics, in cooperation with various hospitals of the city.

Doctor Spielberg Honored.—Dr. William Spielberg, of New York, who has recently returned from Palestine, was guest of honor at a dinner at the Hotel McAlpin.

Dr. Crile Lectures.—Dr. George W. Crile, of Cleveland, lectured on Certain Points in Abdominal Surgery, illustrated with lantern slides, before the Flatbush Medical Society of New York.

Doctor Garrison in New York.—Dr. Fielding H. Garrison, of the Army Medical Museum, held an informal conference in diabetes and insulin at the Academy of Medicine, New York, Saturday, February 21st.

Doctor Kopetsky Honored.—Dr. Samuel J. Kopetsky, president of the Medical Society of the County of New York, will be guest of honor at a dinner March 12th, at the Commodore Hotel. Tickets may be obtained from Dr. Philip Horowitz, 57 West Seventy-third Street.

Open Air Classes.—Twenty cities and one village of New York state, coming under the medical inspection law, maintain open air schools or classes, taking care of nearly one thousand children. The results in improvement of physical and mental health of the children are reported to be very satisfactory.

Doctor Mosher Honored.—Dr. Eliza Mosher, of Brooklyn, will be guest of honor of a dinner at the Hotel Roosevelt, on March 25th, to mark her fiftieth year in the practice of medicine. Physicians and others desiring to attend the dinner may apply to Jean G. Cross, 140 West Fifty-fifth Street, New York.

Babies' Hospital to Join Medical Centre.—Official announcement has been made of the decision of the directors of the Babies' Hospital of New York, to join the new medical centre of Columbia and Presbyterian Hospital. The Hospital has been associated with Columbia for twenty-four years as a teaching centre, and its removal to the new location will give it the better surgical and dispensary facilities it needs.

Endowed Hospital Room for Physicians.—The Physicians Endowed Room Association is endeavoring to raise a fund for the endowment of a room at the Lutheran Hospital, New York, for the use of physicians unable to pay for hospital care. This expense for room and board must be met by a physician himself, even in the institution where he gives his services, and it is the hope of the association to provide at least one room in each hospital for impecunious physicians needing hospital and nursing care.

Lectures on Health Conservation.—At the East Harlem Health Centre, 345 East 116th Street, New York, there will be held Wednesday afternoons at four o'clock, from February 18th to May 20th, a series of lectures on community aspects of health conservation and disease prevention. Dr. Iago Galdston, of the New York Tuberculosis Association, will supervise the lectures, which will be under the auspices of that organization and the Public Health Committee of the Academy of Medicine.

Personal.—Dr. Modie E. Cunningham has been appointed resident physician of the Burke Foundation, White Plains, New York.

Dr. M. Joseph Mandelbaum, of New York, gave by invitation a Demonstration of Lamb's Lung Manikin for Bronchoscopic Study and Practice," before the section on otology and laryngology of the College of Physicians of Philadelphia.

Dr. George W. Duvall, of Owensboro, Kentucky, director of the Daviess County Health Department, has been appointed superintendent of the Central Free Dispensary of Rush Medical College, Chicago.

Dr. George W. Meister has accepted an appointment as superintendent of the Samaritan Hospital, Philadelphia, resigning from his position as superintendent of St. Luke's Homeopathic Hospital.

Dr. Russell L. Cecil, of New York, spoke before the Chicago Medical Society February 11, on Recent Advances in Specific Therapy of Lobar Pneumonia."

Dr. Joseph F. Saphir has received an appointment as attending proctologist to the Jewish Maternity Hospital.

Dr. Hannah M. Stone has been appointed assistant medical director of the clinical research department of the American Birth Control League, 104 Fifth Avenue, New York. Dr. Stone takes the place of Dr Dorothy Bocker.

Foreign Correspondence.

LONDON LETTER

(From our own correspondent)

London, *January 27, 1925.*

TRAINING OF MIDWIVES

With a view to reducing mortality and disability among mothers and infants, the Central Midwives' Board of England and Wales have decided that the period of training for midwives should be extended to twelve months, except in the case of certain trained nurses, for whom the period of instruction will be six months. The new rules which it is hoped will come into operation on May 1st next will require much greater attention to be given to matters antenatal and will provide for the training of pupils of experience both in intern and extern work. These requirements alone, the board states, should go far to affect favorably the health and welfare of both mother and baby. During 1923-24 forty midwives were dealt with by the board under its penal powers to answer charges of malpractice, negligence or misconduct. These forty cases resulted in the immediate removal from the roll of the names of twenty-two women, three of whom were prohibited from attending women in childbirth. Two others were censured and three cautioned, while in three cases no action was taken. In nine instances sentence was postponed. Of the forty cases tried, thirteen were those of women who had neglected to advise medical assistance in cases of ophthalmia neonatorum.

TOXIC CONDITIONS FOLLOWING ETHER ANESTHESIA

At a meeting of the Liverpool Medical Institution held on January 8th last, Dr. R. T. Minnit read a paper on some toxic conditions following ether anesthesia and their successful treatment. He described the symptoms after ether anesthesia in the nondiabetic case as less than but comparable with those occurring in the diabetic. He showed that there was a definite relationship between the hyperglycemia associated with ether anesthesia and the toxic symptoms which follow. He suggested that treatment for these should be on the lines found so successful in the case of the diabetic, and drew the following conclusions from eight selected cases out of about thirty: 1. That there is a definite rise in blood sugar varying with the length of anesthesia. 2. That in the case where the blood sugar falls at the conclusion of the anesthesia to more or less normal, and does not rise again, that the patient suffers little, if at all, from toxic symptoms, such as vomiting, pallor or acidosis. 3. From the sugar tolerance test upon a patient before and after anesthesia, the blood sugar curve is so altered as to show the efficiency of the pancreas is impaired. 4. Patients who exhibit toxic symptoms after anesthesia have a secondary rise in blood sugar synchronously therewith. 5. Upon the administration of insulin to patients with these toxic symptoms, when the blood sugar is brought down they recover. 6. The administration of insulin may have to be prolonged until the blood sugar is reduced, for it is not until then that improvement takes place. 7. The administration of insulin at the end of ether anesthesia can prevent or mitigate the toxic symptoms.

Dr. Pemberton discussed the action of ether in producing hyperglycemia of a maintained type. He pointed out that as Dr. Minnit had shown the carbohydrate tolerance was considerably diminished so that the effect of ether was probably not only glycongenolytic, but also on the islet tissue of the pancreas.

Dr. R. E. Roberts read a paper on the value of x rays in the examination of the stomach and duodenum. His paper was based on a survey of 319 consecutive cases in which the stomach and duodenum were examined subsequently by the surgeon on the operating table. The direct and indirect evidence on which the radiological diagnoses were made was briefly indicated, of forty-seven cases giving radiologically normal findings, only two showed any lesion at operation, in both cases situated at the cardiac end of the stomach. In fifty-four cases where the surgeon found no lesion at operation nine had shown abnormal x ray findings. Suggestions as to the possible explanation of these discrepancies were put forward. Diagnostic x ray evidence of the lesions found at operation had been obtained in 232 of the 250 cases in which a gastric or duodenal lesion was found at the operation; 14—5.6 per cent. showed evidence which was not diagnostic while only 4—1.6 per cent. showed no x ray evidence at all of abnormality of appearance on function of stomach or duodenum.

Dr. G. J. Spriggs congratulated Dr. Roberts on the practical value of the paper. Some years ago he had published a series in which the clinical diagnosis was compared, first, with the diagnosis made after scientific examination, chemical, bacteriological and radiological, and secondly, the ultimate diagnosis arrived at by operation on the subsequent development of the case. The scientific examination altered, added to or modified the clinical diagnosis in more than half the cases. There were just over one per cent. in which the diagnosis after scientific examination, including the use of x rays, proved to be in error, but in all of these the advice given, namely, an exploratory examination, had proved to be wise. He and his radiological colleague, Mr. Marxer, who was present, agreed that irregularities on the greater border, particularly near the cardiac end, sometimes gave rise to difficulty, which, however, generally disappeared on reexamination. The alteration of function was especially important near the pylorus, particularly, as Dr. Roberts mentioned, arrest of the peristaltic wave if carefully observed. He thought that in the pyloric and duodenal regions there would be a larger proportion of cases in which direct evidence of lesion was obtained if patients were repeatedly examined in the prone position at different angles of rotation.

HABITS AND HEREDITY

It is difficult for the laity and not infrequently for medical men always to follow the statements on heredity by authorities as different views are being promulgated at different times. At one time Lamarck and his followers were looked upon as deluded persons, because they believed that acquired characters could be and, in fact, were passed on from parent to child. Orthodox science then laid it down as an axiom that a parent could bequeath nothing corporeal and mental which was not innate in his own frame. The pendulum has swung backward and Professor

McBride now states that habits can be inherited and on this account as generation succeeds generation, education should become easier to the young. It is instructive although somewhat confusing to note how views as to heredity change. We seem at the present time to be returning to the beliefs of our forefathers that a predisposition to many if not most diseases can be transmitted by heredity. Diathesis used to be almost sneered at by the ultrascientific members of the profession. It now appears to be becoming the vogue. There are probably fashions in medical science as well as in treatment and medicines.

RESIGNATION OF SIR HAROLD STILES

It is stated that Sir Harold Stiles has resigned the chair of clinical surgery in Edinburgh University to which he was appointed in 1919. For his cancer research he gained the first award of the Walker Prize of the Royal College of Surgeons of England. The American Surgical Association gave him an honorary fellowship and he received the honor of Knighthood from the King for services rendered during the war.

NEW BOOKS

The *Medical Year Book* for 1925 compiled and arranged by Mr. Charles R. Hewitt, late librarian of the Royal Society of Medicine, was issued recently. This is the second issue. On the occasion of the publication of the first medical annual edited by Hewitt, the work was mentioned favorably in a former letter. Little can be added to the eulogies pronounced then except that the present issue is fuller and has been brought up to date including some important information which was lacking in the first edition. It is wide in its scope, as far as the medical profession here and its activities are concerned, and yet handy in size and may be particularly recommended to the notice of American medical men who visit this country and desire to be well informed as to all that concerns medicine. It is published by William Heinemann, Ltd.

Another book first brought out by the same firm is *Acute Infectious Diseases,* by J. D. Rolleston, M.A., M.D. (Oxon.). This book deals with the commoner acute infectious diseases from the viewpoint of twenty-five years of personal experience reinforced by a study of their literature. It should be said that only those diseases are discussed which are mainly or exclusively notifiable and treated in isolation hospitals. The work is chiefly of a clinical nature but succinct accounts are given of the diseases from the bacteriological and pathological angle, as well as a brief history of each disease. The book is not illustrated because it is the author's conviction that the only satisfactory place to study the cutaneous lesions of the acute exanthemata, the various morbid appearances of the throat and the temperature charts, is at the bedside. In his opinion, and there are a large body of medical men who will echo his views, some excellent textbooks have been disfigured rather than improved by the reproduction of photographs or drawings which show little or convey an entirely misleading impression. The book may be recommended to the medical profession as being what it purports to be, a good clearly written clinical description of the diseases discussed by a man of experience with a description of the other aspects.

Yesterdays, by Lucy Seaman Bainbridge, mother of Dr. William Seaman Bainbridge, which has just come into my hands, is a charming autobiography of a talented woman imbued with that love of travel and intelligent inquisitiveness which seems to be a characteristic of the educated American woman. Mrs. Bainbridge's book is a family book, as all autobiographies are, and tells us among other things that her mother became a medical woman in the days when the practice of medicine was regarded as not befitting a woman. Perhaps the most intriguing part of the book is that in which she narrates her experiences as Nurse Ohio in the Civil War. However, throughout its pages the interest never flags and Mrs. Bainbridge is to be congratulated on relating intimate affairs and great affairs alike in a manner to hold the attention of the reader.

The second edition in French of the *Problem of Cancer,* by Dr. William Seaman Bainbridge, of New York, and translated by Dr. E. Hertoghe, of Antwerp, has been issued recently from the Royal Press of Louvain University. It may be recalled that the first French edition was published at the request of the King and Queen of the Belgians, the King accepting the dedication of the book, and it was the first book to be published at the press of the University of Louvain after its destruction by the Germans. The present issue of this comprehensive work on cancer has been considerably enlarged and thoroughly revised and brought up to date.

LATIN AMERICA LETTER

(From our own correspondent)

Balboa Height, C. Z., *January 10, 1925.*

RESEARCH AT BARRO COLORADO ISLAND

The Panama Canal maintains a research station on Barro Colorado Island in Gatun Lake, where scientists may come for the purpose of carrying on scientific investigations especially in medical entomology and zoology. The United Fruit Steamship Company has renewed its offer, furnishing a number of passes between New York and the Canal Zone to properly accredited scientists, who wish to come to Barro Colorado for study. The passes furnish transportation only, and the traveler must pay for meals. During the past year quite a number of research workers arrived at Barro Colorado and were well satisfied with the experimental station. The station is in charge of Dr. James Zetek, entomologist of the Department of Agriculture.

IMPROVEMENTS IN CHILEAN PORTS

The Chilean Government recently asked for bids for construction of improvements at the ports of Lebu, Constitucion, and Antofagasto. These contemplated improvements will have a great bearing upon the sanitary condition of the ports. Among the improvements considered will be the erection of rat proof wharfs and warehouses. Valparaiso and San Antonio have already been equipped with rat proof docks. The amount of expenditure involved is estimated to be around $5,000,000 gold. Rat plague is very prevalent along the west coast of South America and these improvements will go a long way to help in eradicating this disease. The

recent reorganization of the Government of Chile exemplifies with great clarity the progress that is being made in that country. The most noted improvement is the entire reorganization of the health department and the appointment of Dr. Alejandro del Rio as Minister of Health and first chief of the new ministry. He is well qualified scientifically for the position and has been active in the organization of the existing good hospitals throughout Chile. He is one of the editors of the government quarterly, *Revista de Beneficencia Publica.*

VITAL STATISTICS OF THE CANAL ZONE

A total of 144 deaths occurred during the month of November, 1924, among the population of the Canal Zone and in the cities of Panama and Colon. This is equivalent to an annual death rate of 13.49 in a thousand. The leading causes of death were: tuberculosis (various organs), thirty-three; pneumonia (bronchial and lobar), thirty-three; diarrhea and enteritis (including colitis), seven; there were four deaths from cancer and two deaths from dysentery. Of the total deaths, thirty per cent. occurred among children under five years of age. There were sixteen deaths among nonresidents of the Isthmus, but these are not included in those statistics. There were 333 live births reported during the month and twenty-one still births. Including the still births, this is equivalent to an annual birth rate of 33.15 in a thousand of population. Deaths among children under one year of age numbered thirty-one, giving an infant mortality rate of 93.09 in a thousand live births.

The total number of malaria cases reported during the month was ninety-four. Of these two were reported from Panama City, one from Colon, fifty from the Canal Zone sanitated area and forty-one originated outside the sanitated area. Of the total, nine were employees, thirty-one were non-employees and fifty-four were Army and Navy personnel. There was one death from malaria.

ISTHMIAN CANAL ZONE MEDICAL ASSOCIATION MEETING

The 216th meeting of the Isthmian Canal Zone Medical Association was held at the Amcon General Hospital at 8.00 p. m., Tuesday, December 16, 1924. An interesting program was presented.

JAPANESE COMMISSION ARRIVES AT CANAL ZONE

A Japanese diplomatic commission composed of physicians and other scientists recently arrived at the Canal Zone for a week's visit. The commission has among its members, Dr. Itchioyama, Dr. J. Hatori, Dr. Moruki, Dr. Koshiga and Dr. Ruoka. These distinguished scientists are making a study of health and economic conditions in the countries of Central and South America. Dr. J. Hatori is at present Chief Health Officer of the Island of Formosa, one of the Japanese possessions, and is well known to many American physicians on account of his extensive writings in American Scientific Journals, particularly on the subjects of malaria and rat bite fever. He is one of the leading biologists of Japan.

The commission has finished a study of conditions in Central America and have now started on their tour of South America. It will take about a year to make the study before they return to their own country. Dr. Hatori will later go to the United States for the purpose of visiting the surgeon general of the United States Public Health Service, and officers connected with the research department of the Hygienic Laboratory. Coincident with the arrival of the commission, three Japanese warships also visited the Canal. Seven medical officers of the fleet, together with the commission, were entertained by officials of the Health Department and shown over the Zone, especially the hospitals, sanitary and quarantine activities and a visit to the Palo Seco Leprosy Station.

UNITED STATES BOMBING PLANE DESTROYED IN COSTA RICA

Four army aviators on a visit to Costa Rica fell a distance of one hundred feet when their Martin bomber crashed to earth just outside of San Jose, Costa Rica. The big machine burst into flames when it struck the earth and was entirely consumed including all the equipment of the army men. How they escaped instant death is one of the miracles of aviation and a mystery to the medical men who were rushed to the scene of the accident. After the plane had flown about a mile and was one hundred feet in the air, it apparently struck an air pocket, for although the propeller and engine were going as usual, the bomber seemed to settle to the ground out of control of the pilot. It hit with a crash throwing the four men out. The gas tank burst and in an instant the plane was in flames. The only injuries sustained by the aviators, were a few bruises about their heads and limbs. They returned by steamer to the Canal Zone, none the worse for their experience.

Letters to the Editor.

VAQUEZ'S DISEASES OF THE HEART

BRONXVILLE, N. Y., *February 16, 1925.*

To the Editor:

I appreciate the cordial praise of Vaquez's *Diseases of the Heart* in your issue of January 21st. In so kind a review, it may be ungracious to cavil at a minor point but I cannot permit my author to rest under the imputation of the error that you ascribe to him. Your reviewer says: "Dr. Laidlaw's translation is faithful and fluent. Indeed, he even translates a mistake from the original French to the effect that Stephen Hales's pioneer blood pressure studies were made on a dog, when in fact that reverend gentleman conducted his experiments on a mare."

If it were so, it was a grievous fault and grievously shall Cæsar answer it; but it is not so. Everybody has heard of Stephen Hales's mare; apparently not everybody has heard of Stephen Hales's dogs, twenty of them, used in the same experiments. This is not surprising, for Hales's book was published in London in 1733 and a French translation in Geneva in 1744; copies are rare; the dogs are mute; and modern physiologists speak only of the mare. In this book, *Hemostaticks,* on page 42, Hales tabulates the results of his experiments on two mares, one gelding, one ox heart, one sheep, one doe and the twenty dogs aforesaid.

GEORGE F. LAIDLAW.

Book Reviews

PLASTIC SURGERY OF THE FACE

Facial Surgery. By H. P. Pickerill, C.B.E., M.D., M.S. Introduction by Sir W. Arbuthnot Lane. New York: William Wood and Co. Edinburgh: E. & S. Livingstone, 1924. Pp. 160.

Dr. Pickerill was in charge of the New Zealand section at Queen Mary's Hospital, Sidcup, England, and consequently had a wide and varied experience in procedures for the relief of war injuries to the face. The present work contains many photographs representing cases treated at Sidcup, forming a useful addition to the record furnished by Gillies and others of the Sidcup staff. The work is not by any means, however, a glorification of war surgery. In fact the author concedes that in some instances war practice was "many years behind the recognized surgical teaching." What he does urge, and what he sets out to exemplify, is the outstanding lesson of the war hospital experience, namely, that "there are few, if any, cases, however extensive, to be regarded as beyond restoration by purely surgical measures and from the patient's own tissues"; and that "fresh possibilities and new fields are opened up" by the successes already attained. It is in this sense that Dr. Pickerill has classified the various problems presenting themselves for the care of the plastic surgeon, with very thorough discussion of all methods of repair.

A valuable contribution is that in which the author deals with the covering of defects resulting from the excision of malignant growths, to demonstrate that such growths "may be much more widely excised than was formerly thought possible," and that, since the tissues removed can be suitably replaced, this need not result in permanent disfigurement, or loss of function. All this is quite in line with what is now well recognized in American practice.

At times, in reading this work, one feels that the advance in plastic surgery has been so rapid that in certain fields there are already notable advances upon the methods the author describes. As against that, there are cases here given which point clearly to the successful extension of plastic surgery into areas in which, until very recently, its use was not contemplated.

The section on principles and methods is well arranged and contains much that may be helpful in practice.

BISMUTH TREATMENT OF SYPHILIS

Le Bismuth Dans le Traitement de la Syphilis. Par C. Levaditi. Avec 31 Illustrations and one plate. Paris: Masson et Cie., 1924. Pp. 316.

In this monograph Levaditi discusses most thoroughly the progress that has been made in the employment of bismuth in the treatment of syphilis. In spite of the ever growing literature on this phase of antiluetic therapy, it is surprising that so much in the way of clinical and theoretical data can be accumulated within the covers of a single volume on a subject of such recent development.

The author needs no introduction to medical men. For several years past, since the introduction of bismuth as an antiluetic, he has worked assiduously on the subject of bismuth therapy and he presents his conclusions in this volume. Summarizing these views briefly, he advocates the use of bismuth as an adjuvant to the arsenicals and as a substitute for them in those cases in which the latter cannot be employed; neoarsenobenzol and bismuth, in alternation, constitute the ideal treatment for lues; bismuth is best given intramuscularly, inasmuch as the intravenous method of administration has not yet been made feasible; properly administered, the injection is absolutely painless; the Wassermann reaction is quickly controlled by bismuth; there are no deleterious after effects or reactions after its use; nitritoid crises never occur after bismuth injections; thirty-six bismuth preparations are mentioned as being used in France, but the author seems to favor trepol and neotrepol, as the most efficient and least irritating.

The book is well written and fully covers the ground. It is a work with which everyone engaged in the treatment of syphilis should be intimately acquainted.

MALIGNANT NEOPLASMS

Die Klinik der bösartigen Geschwülste. Herausgegeben von Dr. P. Zweifel, und Dr. E. Payr. In drei Bänden. Mit Textabbildungen und farbigen Tafeln. Band I: Allgemeine Geschwulstlehre, Haut, Nervensystem, Kopf und Hals. Mit 204 Textabbildungen und 33 farbigen Tafeln. Leipzig: Verlag von S. Hirzel, 1924. Pp. xx-860.

This is the first of three volumes comprising a stupendous work on malignant tumors, intended for use by the general practitioner, the hospital physician and the specialist. This work presents the present state of our knowledge regarding the pathogenesis, early diagnosis, tissue peculiarities, methods of spreading, symptomatology, clinical course, diagnosis and methods of treatment of malignant neoplasms in the various organs of the body; also the postoperative treatment of the late complications by the general practitioner. All these subjects are discussed with the underlying thought of the curability of cancer, the cause of which is being sought so universally. It appears as though this goal was gradually being reached. The statistical increase in the number of cancer cases may be partially explained by better and more frequently correct diagnoses. The absence of pain in precancerous conditions should be a warning signal. The fact that cancer is at first only a local disease is emphasized and early diagnosis and treatment are therefore imperative. In this work cancer is considered as a general disease and the peculiarities of tumor development in the different organs as to course, dissemination and final result are discussed, and from these a pathological physiology of malignant tumors is built up.

Each author gives his own personal experiences, with the result that this work is a mosaic of impressions of the various clinicians, all specialists, unified by the bond of pathological anatomy and biology. Although surgery has so far given the best results, surgery and irradiation therapy should supplement each other, and serum and vaccine therapy should not be neglected. The illustrations are beautiful and numerous and the colored plates deserve special mention. Only such references (especially those not

German) are given in the bibliography as are accessible to German readers, but a number of American authors are cited.

Borst discusses the general pathology of malignant tumors and he considers malignancy as the resultant of cell degeneration, the surroundings of both these cells and the constitution and predisposition. The causes may be general, local and cellular. After discussing the general morphology and general biology of malignancies, he takes up the histogenesis, classification and the nomenclature of malignancies; also the sarcomas and carcinomas and the special forms and mixed forms of malignancies. Carcinoma and sarcoma of the skin are described by Delbanco and Unna. Xeroderma pigmentosum is assigned to Rille. Küttner writes about the malignancies of the scalp and skull. Malignancy of the nervous system is the work of Pette. Payr takes up the subject of the operative and irradiation treatment of cerebral malignancies. Those of the eye are described by Sattler; those of the ear, nose and accessory nasal cavities, pharynx and larynx by Knick. Malignancies of the maxilla, tongue and oral cavity are discussed by Partsch and those of the salivary glands by Heineke. Kocher writes about the malignancies of the thyroid, parathyroid and carotid glands and about malignant branchiogenic tumors.

This is undoubtedly the most complete and authoritative work on the subject of malignant tumors.

BASAL METABOLISM

Basal Metabolism in Health and Disease. By Eugene F. Dubois, M.D. Illustrated with seventy-nine engravings. Philadelphia and New York: Lea and Febiger, 1924. Pp. 372.

The author is one of the foremost American workers in the field of metabolism. He sets forth in this book an authoritative and comprehensive review of our present knowledge of this subject. The first part of the work deals with metabolism in health, the second with metabolism in disease. The exposition of fundamental principles will appeal to the beginner for whom the book is primarily intended. There are, however, numerous historical surveys of special topics which will undoubtedly interest the more advanced student as well. The presentation is that of a competent scientist who tells not only how much in this new field is known, but also how much is still the subject of speculation, debate and active investigation.

GOLD TREATMENT OF TUBERCULOSIS AND LEPRA

Die Goldbehandlung der Tuberkulose und der Lepra. Klinische Erfahrungen mit Krysolgan. Von Adolf Feldt. Dritte vermehrte Auflage. Halle a.S.: Carl Marhold, 1924. Pp. 50.

Krysolgan is an aminoaurothiophenol carbonate of sodium, containing fifty per cent. gold, which is injected intravenously. It is a specific remedy as it produces focal reactions after the administrations of therapeutic doses. It is contraindicated in cases of tuberculosis with high fever and in cases that have advanced too far. The doses are gradually increased from 0.05 gram to 0.5 gram. It is indicated in tuberculosis of the lungs, eye, larynx, nose and throat, skin, in psoriasis, surgical tuberculosis, tuberculosis of the gastrointestinal tract, urinary organs and in lepra. It may also be used in conjunction with mercury and it is indicated as a preliminary treatment to tuberculin therapy. It is applicable in ambulant cases.

In this edition the author collected the numerous reports on the clinical and experimental studies on the treatment of tuberculosis and of lepra with krysolgan which he found scattered throughout the literature. A complete bibliography is appended.

BICKHAM'S SURGERY

Operative Surgery. By Warren Stone Bickham, M.D., F.A.C.S. In Six Volumes and a General Index. Volume IV: Pericardium, Heart, Other Endothoracic Operations, Abdominopelvic Wall. Herniae-Peritoneum; Omentum-Mesentery-Stomach, Pancreas, Spleen, Liver, Biliary, General Intestinal, Appendicocecal Tract. With 772 Illustrations. Pp. 842. Volume V: Colorectoanal Tract, Kidney, Suprarenal Glands, Ureter, Bladder, Male Urethra, Penis, Scrotum, Testicle, Spermatic Cord. With 1118 Illustrations. Pp. 880. Volume VI: Seminal Vesicles and Ducts, Prostate, Female Urethra, Perineum and Genitalia, Pregnant and Puerperal Uterus, Ectopic Pregnancy, Operations on the Newly Born, Deformities. With 1224 Illustrations. Pp. 989. Philadelphia and London, W. B. Saunders Company. 1924.

On reviewing the last three volumes of this system of surgery, one is impressed by its general excellence. It is infinitely superior in completeness of detail, in illustrations and in the general subject matter to any recent system of surgery. It is very complete and is accompanied by a separate volume which is the general index. This makes a very satisfactory arrangement. It seems almost impossible that one man could have covered this entire field; arranged and provided for the illustrations, and reviewed the anatomical details which are given at the beginning of each article.

One must give credit to Saunders for the tremendous expense which must have been involved in reproducing the many excellent illustrations. One might always complain of omissions and certain ones occur in these volumes. For instance, there is no reference to the operation of sympathectomy as described by La Riche. The reviewer considers this system of surgery an important part of every surgeon's armamentarium.

CLINICAL INTERPRETATION OF EYE SYMPTOMS

Sémiologie oculaire. Le Diaphragme iridociliaire. Par Félix Terrien. Paris: Masson et Cie, 1924. Pp. 1-234.

This study constitutes the second volume of the author's *Sémiologie oculaire,* and covers the anatomy, physiology, and pathology of the iris and ciliary body. The subject is treated from the point of view of the clinician, the author's chief aim being the clinical interpretation of the symptoms as they present themselves in the many pathological conditions of the two organs. Considerable space is devoted to the functional disturbances of the iridociliary curtain, in which the subject of the pupil and its variations in disease is gone into most exhaustively. Iritis and iridocyclitis, contusions of the iris and ciliary body, tumors and malformations, and variations in ocular tension, form the other chapters of this work. The value of the text is considerably enhanced by numerous illustrations, some of which, as for instance, tuberculosis of the iris on page 133, persistent pupillary membrane on page 180, and a few others, are particularly interesting.

INTERNATIONAL CLINICS

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Articles by Leading Members of the Medical Profession Throughout the World. Edited by Henry W. Cattell, A.M., M.D., Philadelphia. Volumes III and IV. Philadelphia and London: J. B. Lippincott Company, 1924.

The usual high standard maintained in the selection of the articles and papers for these clinics, has been maintained in the volumes under review. In Volume III the outstanding article is one by B. Sherwood Dunn, of Paris, on The Evolution in the Treatment of Syphilis: Past and Present. This article would make a fine monograph on the modern treatment of lues, if published separately. Another highly interesting contribution is one by Harry Eaton Stewart, on The Use of Diathermy in Pneumonia, in which this procedure is warmly advocated as a most useful adjuvant in the treatment. It is declared to be absolutely safe in competent hands, brings almost certain symptomatic relief and has apparently lowered the mortality in a group of cases which included all types.

Volume IV contains twenty-two interesting papers on varied subjects, including a concise and thorough résumé of the treatment of diabetes by insulin, by its discoverer, F. G. Banting, of Toronto. His views are summed up in the last brief paragraph of his article: "Insulin is not a cure for diabetes; it is a treatment. It enables the diabetic to burn sufficient carbohydrates, so that proteins and fats may be added to the diet in sufficient quantities to provide energy for the economic burdens of life."

Ernest Schulmann, of Lyons, France, has an unusually interesting article on Syphilis of the Thyroid Gland, with Special References to Exophthalmic Goitre. This is well worth reading. Other contributions of note are made by P. J. Flagg, on Ethylene, by Alfred Hand, on The Effect of Tonsillectomy on Existing Visceral Disease, and by Sterling Bunnell, of San Francisco, on The Nature of Intestinal Obstruction. Both volumes are freely illustrated.

MORE SEMBAL

The House of Prophecy. By Gilbert Cannan. New York: Thomas Seltzer, 1924.

The second novel in the Sembal series, to those who know the first, probably carries on the penetrating study of this meteoric young Hebrew in a fashion even more cumulative. A story rather intense, even sympathetic, has been superimposed upon a sociological framework. Racial trends have become traits, inhuman forces, environment, family, postwar chaos have been not humanized, but puppetized. There is a symbolic virtue in Cannan's parable which tends to obscure its qualities as a tale of human interest. The economic war in England between Jew and Gentile is brought home to the reader with perhaps more telling force than textbooks on the undercurrents of sociological research could possibly do. We suspect just what the shortcomings of the old order were. We can interpret intelligently the new moves in the great game of psychological interplay between two powerful races. But the emotions of an American are only vaguely brushed if at all. And the story therefore does not thrill us much.

An imprisoned philosopher and a rare young English girl, meshed in the toils of attraction Sembal and all he represents of struggle, intellect emotionalism, apart from sheer weird personality county families shut off in the industrial towns they called into being and that have now outgrown the feudal age in which those barons still long to live finally the triumph—implied—of this member of the Jewish race who always gets what he wants this makes the story.

But if you like your economics painlessly, if you would rather learn from dramatized cold facts than feel them out for yourself in all their hopelessness by all means follow the fate of Sembal and learn therefrom the destiny of England.

CHILD PSYCHOLOGY

Love in Children and Its Aberrations. A Book for Parents and Teachers. By Oskar Pfister. Translated from the German by Eden and Decar Paul. New York: Dodd Mead and Company, 1924. Pp. 576.

In spite of certain minor restrictions this work of Pfister's is of fundamental value. Attention is called to the many classical components of the psychological makeup of the child. Although the book is somewhat bulky, it is clearly written and every paragraph has its valuable and suggestive material. At times Pfister lays undue stress on the transient ethical and moral values but this is a universal fault and no doubt more apparent in his work on account of his natural conditionings. The physician, the educator, the parent, and the student of human behavior will do well to study this last contribution from the pen of one of the most sincere workers in abnormal psychology.

Medicoliterary Notes.

One of the deplorable facts brought to light by the present widespread interest in preserving the fast disappearing wild life of this country, and, in fact, of the whole world, has been the great prevalence of lead poisoning among game birds. This is caused by the birds' finding in the mud about shooting points and blinds in marshes and on shores of lakes and streams a large quantity of expended shot which they eat. The amount of this shot is estimated as enormous owing to the greatly increased number of hunters. The birds that have suffered most are whistling swans, mallard and canvas back and pintail ducks.

* * *

According to interviews recently reported in the daily press, Dr. Arthur Selby, a medical missionary from England who has returned to that country for a vacation after long service in Central Africa, states that it has recently been learned in Nyasaland that a certain species of dragonfly preys on the deadly tsetsefly which causes the socalled sleeping sickness. Central African physicians are now engaged in cultivating this parasite on a large scale, hoping they may thus be enabled to stamp out the pestilence.

* * *

That the United States record of ten thousand murders a year is too low, and that the only adequate method of meeting the problem is for the Government to tabulate data periodically from court records, were statements made recently in an address by Dr. Frederick L. Hoffman. He believes that many cases of so recorded accidents are really homicides.

* * *

The report to the House of Delegates of the Commission on Cancer of the Medical Society of the State of Pennsylvania has been issued as a reprint from the *Atlantic Medical Journal for* September, 1924. In 1910-11 the commission made a survey of the cancer situation in Pennsylvania with a view especially of showing the extent of

delay that cancer cases went through before seeking adequate treatment. It was decided to make in 1923 a similar survey to learn whether cancer education pays and how previous efforts could be improved upon. The tabulated report shows, in the large decrease in delay of treatment of every form of cancer, that education does pay; and the commission recommends as the best method of improving upon former efforts the setting aside of a special fund to enable the poor to have adequate examination and diagnosis without the present usual exorbitant charges.

Stuart P. Sherman, editor of *Books*, the Herald Tribune's literary supplement, has an excellent article on Pierre Loti in the issue of January 18th.

* * *

Red Cross workers in Manhattan have sent to the Library of Congress 12,300 pages of Braille reading material for distribut on at once among blinded soldiers. The gift comprises short stories, magazine and newspaper articles, novels, history, textbooks, and scientific works. It took nearly five thousand hours, the equivalent of more than two years' work, for the Braille operator to prepare them. The work was taken over by the Red Cross because no commercial process has been devised for making books for the blind which would be within reach of the pocketbook of the average blind person.—*New York Times.*

* * *

In Paris it is required by law that a doctor be present at every theatrical performance. Most French managers refuse to employ regular house physicians, so seats are presented instead to doctors so that the law may be complied with. Some of the managers are now complaining that often the doctors do not come, but hand their tickets to friends who are not of the profession. The managers now propose, according to the *Living Age*, to make arrangements with physicians whose offices adioin their theatres so that they will be immediately available if called upon. "The doctors, who are perfectly satisfied with things as they are, protest vigorously that, attending the theatre as they have been doing, they have treated two hundred cases during the last theatrical season—which seems to show that they earn their seats."

* * *

The famous burglar, Williams, who once broke into the house of Mark Twain, has written a book about his life, *In the Clutch of Circumstances*, recently published by Appleton. He is no longer a burglar, but "reformed" many years ago, and has since become a very successful business man—which seems logical!—devoting most of his savings to helping criminals who had a wrong start in life to begin over again. Williams was recently guest of honor at a banquet given him by the leading business and professional men of Hartford, Conn.

* * *

Since many inquiries received by the National Committee for Mental Hygiene are of general interest, a column of such questions has been opened in the monthly *Mental Hygiene Bulletin*, in which such as may be answered briefly will be published each month. An appended section will give suggestions as to what to read.

* * *

A fertile field for psychoanalysis should be the forthcoming novel, *Cheating the Devil*, by Juanita Burbridge, to be published by Nicholas Brown. It has been announced that this novel is based upon a series of dream experiences which the author had while she was very ill in 1918. One of the incidents of the book is said to be the exact prediction, to the day and hour, of the ending of the World War.

* * *

How many of us know that Peter Mark Roget, of *Thesaurus* fame, was for several years physician at the Manchester Infirmary in Manchester, England, where he was one of the founders of the Manchester Medical School? Roget was born in 1779, and lived to be ninety, preserving health and vigor throughout his long life.

* * *

Dr. C. G. Kerley has an article in the February *McCall's Magazine on* The Child Who Has Rickets.

* * *

The *American Mercury* for February is a number of special interest. It contains a short story by James Branch Cabell called Above Paradise; an article, Up from Methodism, by Herbert Asbury; The Drug Addict, by Robert A. Schless; Walt Whitman Neologisms, by Louise Pound; George Moore at Work, by Barrett H. Clark; Golden Wedding, a story by Ruth Suckow, and other characteristic contributions.

* * *

According to the Parisian press, a trial has been asked is *The Borderland; Some Problems of Insanity*, by Dr. Theodore Bulkeley Hyslop.

* * *

The man who complains because he has to pay ten cents for his Sunday paper may find some consolation in the thought that the Russian muzhik who craves the luxury of a daily journal has to make a rather heavier sacrifice to obtain it. The subscription price of *Pravda*, the official Communist daily of Moscow, is thirty poods, or more than a thousand pounds of rye per annum. This is nearly the normal crop on a dessiatine of land. Since the average farm is four or five dessiatines in extent, a peasant subscriber—assuming him to exist—would have to pay approximately one fifth of his farm income for his daily paper.—*Living Age.*

* * *

According to the Parisian press, a trial has been asked for in the Appellate Court to clear the name of Bluebeard, who was burned to death in 1440 for sorcery and the murder of 800 women and children. Several historians and members of the Academy, it is claimed, have found proof that the Baron de Retz, Bluebeard's original, was a Marshal of France and companion in arms of Joan of Arc, and was in reality a most gentle knight. Part of the proof was the finding of a vein of gold in a rock under the castle of Machecoul, one of the Baron's strongholds. One of the crimes which had most weight in his trial for heresy was "the manufacture of gold" supposedly made out of the blood of the 800 victims. This find is considered to be sufficient evidence for a new trial.

* * *

The press reports that the feelings of the Bulgarians are greatly wounded by the recent production in Berlin and Vienna of Bernard Shaw's *Arms and the Man*, where it was seen by sensitive Bulgarian students. The play had already been cut by the producer at the request of the Bulgarian Minister, who complained that it ridiculed the Bulgarians. Mr. Shaw in a letter to the editor of the *Berliner Tageblatt* is quoted as having stated that he greatly regretted that the play had wounded the susceptibilities of the Bulgarian students, but he asked them to remember that it was the business of the writer of comedy to wound the susceptibilities of his audience. The classical definition of his function was "the chastening of morals by ridicule." "When the Bulgarian students, with my sincerely friendly assistance," he concludes, "have developed a sense of humor, there will be no more trouble."

* * *

The manuscript of a book of forty thousand words has been taken down in shorthand and transcribed by a typist blind from birth. She is employed by the National Institute for the Blind in London, and used in accomplishing this unprecedented feat a shorthand machine which makes an impression in Braille characters on a ribbon of paper. These notes were read with the left hand in as short a time as that taken by a seeing typist in consulting her shorthand notes.

A study has recently been made by Dr. Thomas H. Haines, director of the Division on Mental Deficiency of the National Committee for Mental Hygiene, of the special training facilities for mentally handicapped children in the public schools of the United States. This study outlines the progress in making such special provision, and gives such data as the number of these classes, their teachers, and pupils enrolled. In the 430 cities and other school districts included in the study, there were found to be nearly 46,000 children and 2,492 teachers in such special classes. From the data given it is estimated that there are over 900 000 mentally defective and borderline defective children in the public schools of this country, in addition to the 70,000 children now in special classes or state training schools for mental defectives.—*Mental Hygiene Bulletin.*

Abstracts from Current Literature

DERMATOLOGY

Acute Disseminated Lupus Erythematosus.—Chester S. Keefer and Augustus R. Felty (*Bulletin of the Johns Hopkins Hospital,* September, 1924) report three fatal cases presenting the typical clinical picture and course of acute disseminated erythematous lupus, in two of which autopsies were performed, and detailed descriptions of the findings given. The clinical features were similar in all the cases, the syndrome presenting rather a distinct entity as far as clinical observation was concerned. The only constant pathological feature common to both of the autopsied cases was small groups of tuberculous lymph glands; but no extensive tuberculous lesions were found. In one case, tubercle bacilli of the human type were recovered from a lymph gland which did not show the histological lesion characteristic of tuberculosis.

Effect of X Rays on the Skin of Vitally Stained White Mice.—Gerty T. Cori (*Journal of Experimental Medicine,* May, 1924) reports that epilation occurred earlier in vitally stained white mice than in control mice, rayed for the same length of time. The amount of x ray causing total spontaneous epilation of the skin of the mouse is suggested as an x ray unit for that animal, which corresponds to four to five human erythema doses.

Xeroderma Pigmentosum.—Arnold R. Rich, Wilburt C. Davison and Carl H. Greene (*Bulletin of the Johns Hopkins Hospital,* September, 1924) describe a case of xeroderma pigmentosum, developing at the age of two years, in which the lesion was least apparent over the abdomen, buttocks, and back, and most marked over those areas that are usually exposed to sunlight, particularly the face, the neck, and the backs of the hands. The course of the case demonstrated the unfavorable influence of radium therapy, except for a transitory improvement after the second and fourth treatment. A discussion of the skin lesions is given.

Radiodermatitis and Its Treatment.—Arthur U. Desjardins and Fred L. Smith (*New Orleans Medical and Surgical Journal,* November, 1924) say with reference to the treatments of radiodermatitis:

1. The mode of treatment depends on the location of the burn, the looseness of adjoining tissues, the thickness of tissue, and the blood supply.

2. Hyclorite dressings are exceedingly beneficial in cleansing the wound, and seem to stimulate the epithelium. At least we do not believe that epithelial cells are deterred from proliferating by the dilutions used. Hyclorite is preferable to Dakin's solution, the chemical qualities of which are too inconstant.

3. Sunlight in conjunction with wet dressings is very beneficial.

4. Paraffin dressings permit the patient to get about, protect the wounds, and apparently epithelium grows luxuriantly under it, if the surface is free from bacterial products. The dressing should be changed every twenty-four hours.

5. When a film of whitish exudate appears, the use of the wet hyclorite dressings is indicated, and in the course of two or three days, the exudate will usually disappear. The use of paraffin dressings may then be resumed.

6. In the chronic radiodermatitis of radiologists, halfway measures are pernicious. Early radical measures are safer in the long run, and sentiment should not influence the decision as to treatment.

Production and Significance of Cutaneous Allergy to Pneumococcus Protein.—George M. Mackenzie and Shutai T. Wood (*Journal of Experimental Medicine,* January, 1925) produced by intracutaneous injection of guinea-pigs with an alkaline extract of pneumococcus in about two thirds of the animals an allergy with a skin reaction similar to the allergic skin response of tuberculosis. Continuance of the intracutaneous injections after the appearance of allergy results in its disappearance. The skin ceases to react. Neither the animals manifesting skin allergy nor those in which it fails to develop show any significant alteration in susceptibility to pneumococcus infection by intraperitoneal inoculation. Similarly, animals desensitized by continuing the intracutaneous injections after the appearance of allergy show an unaltered susceptibility.

Insulin and the Skin.—Ernst F. Miller (*Journal of Laboratory and Clinical Medicine,* June, 1924) injected rabbits simultaneously with equal amounts of insulin taken from the same bottle, the only difference being that one rabbit was injected subcutaneously, and another intradermally. A decided difference between the results of subcutaneous and intradermal injection was noted. The effect of an equal dose of insulin is considerably prolonged if given by the intradermal route. The skin as an individual organ is partly responsible for this effect, also the factor of resorption plays an important part, but these factors alone will not explain the phenomenon. Experiments quoted indicate that the fatal dose for intradermal injections may be higher than the fatal dose for subcutaneous injections.

Etiology of Erythema Nodosum.—Benvenuto Coglievina (*Wiener klinische Wochenschrift,* April 24, 1924) states that there is no etiological relationship between erythema nodosum and tuberculosis. Inasmuch as both of these conditions show a predilection for their appearance or exacerbation during the spring and autumn, erythema nodosum may become a provocative of tuberculosis, just like measles, pertussis, and other infections. Experiments with the blood of erythema patients and the punctate of erythema nodules have led the author to the belief that an attenuated scarlet fever infection has some connection with the condition. It is contagious, but to a much less degree than scarlet fever. The rare sequelæ, such as endocarditis, pleurisy and meningitis, must be feared because of their severity.

Present State of Knowledge of the Etiology of Herpes Zoster.—B. Lipschütz (*Wiener klinische Wochenschrift,* February 21, 1924) found cellular inclusions, which he calls chlamydozoa, which findings were also observed by several other investigators. The inoculation of these bodies into the cornea of the rabbit is not possible in every case. The best condition and method of inoculation is not as yet known. The close relationship between zoster and varicella is very significant. Protection from varicella can be accomplished through cutaneous and intracutaneous inoculations with zoster material. If this is found to occur in a large material, there can be no doubt that zoster is an infectious disease.

Leprosy, a Selfhealing Disease.—Ernest Muir (*Lancet,* February 9, 1924) draws the following conclusions: 1. Leprosy is a selfhealing disease, in typical cases of which immunity is gradually produced. 2. Delay in immunity production is due to the nature of lepra bacilli which are able to multiply with few or no signs of local or general toxemia. 3. During the first two stages of leprosy it is most important to restore the lowered tissue resistance, otherwise the disease may pass on into the third stage. 4. In the third stage, where immunity has been produced, it is important to bring about moderate reactions so as to hasten the resolution of the lesions before deformity and disablement can take place. 5. In cases which have passed through the third stage an absolute cure may be hoped for as far, in many instances, as the active disease is concerned; while in cases which have recovered without passing through the third stage the cure can only be considered a relative one, recurrence being possible should the tissue resistance be seriously lowered at any future time.

Etiological Relationship Between Warts and Pointed Condylomata.—E. Frey (*Schweizwische medizinische Wochenschrift,* February 28 and March 6, 1924) states that the common hard and the flat juvenile warts, just as the pointed condylomata, are inoculable and have a probable uniform etiology. The various forms of warts are apparently due chiefly to the histological structure of the site of their origin. The varying behavior of the flat warts may be best explained by a different manner of reaction of the skin as the result of a congenital or acquired predisposition. The following factors speak in favor of the assumption of an etiological unity of warts and pointed condylomata: 1, The histological similarity; 2, the frequently simultaneous occurrence of both the hard and flat warts and of the pointed condylomata in both sexes and in the same individuals; 3, the similar behavior of these structures to certain therapeutic remedies (mercury, arsenic, surgical removal and röntgenotherapy); 4, the inoculability of warts and pointed condylomata and the approximately equal period

of incubation, as well as the transition between the two types of warts and the pointed condylomata following autoinoculation and artificial inoculation, particularly the development of the flat and common hard forms of warts after the inoculation of condyloma material.

Infantile Eczema and Thyroid Insufficiency.—P. Bezy (*Presse médicale,* April 30, 1924) notes that aside from the exciting causes of eczema in infants, such as overfeeding and changes in the maternal milk, there are also predisposing causes, such as tuberculosis, syphilis, and, in some instances, thyroid insufficiency. He reports the case of a child of eight months with severe, refractory eczema and signs of hypothyroidia. Thyroid treatment rapidly relieved both disturbances.

Mongolian Blue Spot with Deformities.—Otto Bruch (*Monatsschrift für Kinderheilkunde,* June, 1924) asserts that the appearance of Mongolian blue spots does not indicate the occurrence of an admixture of Mongolian blood in the ascendants. Inasmuch as the large, pigmented Mongolian cells also appear in the white race during definite stages of the embryonal development, some of the Mongolian blue spots must be interpreted as cases of spontaneous atavism. The frequent coincidence of Mongolian blue spots with other malformations may also be explained as germinal injury, which keeps the organism back to an earlier stage of development.

Repeated Serum Rashes.—A Moussous (*Médecine,* August, 1924) has met with nineteen instances of recurring serum eruptions in the last three years. The condition seems to be far more common than formerly. In fifteen cases diphtheria antitoxin and in four antipneumococcus serum had been used. The first eruption appeared from five to fourteen days after the beginning of serum treatment, and the interval between the first and second eruptions ranged from five to twelve days, being most commonly six days. The amounts of serum injected had, in conformity with present practices, rather large, viz., from 60 to 150 mils, given in the course of two to four days. The eruption was generally polymorphic, and the second rash was not necessarily of the same type as the first. The second was usually the more pronounced and the more apt to be attended with manifestations of serum disease.

Epithelization of the Maxillary Sinus.—J. E. Sheehan (*Surgery, Gynecology and Obstetrics,* September, 1923) summarizes his further report on epithelization as follows: The advantages of epithelization of the maxillary recess after the removal of disease are:

1. That the mucous membrane is replaced by skin which assumes some of the function of the membrane.
2. That the formation of scar tissue is prevented.
3. That weeks and possibly months of irrigations are rendered unnecessary.
4. That the cavity is not packed with gauze and after-treatment is consequently short and not painful, with little local or general reaction.
5. That the skin changes its character after a period of weeks, assuming a pinkish white color.
6. That the patient is returned to a state of health in a comparatively short period of time.

In view of the fact that the subject is still in the realm of experimental work the author firmly believes the results obtained are most gratifying and, in concluding this account of his personal experience in connection with the surgery and epithelization of this recess, he desires to record his conviction that, by fair and constructive criticism, one may advance the methods described to a stage where complete success will be the average prognosis where they are used.

Röntgenotherapy of Skin Diseases.—Herbert Fuhs (*Wiener klinische Wochenschrift,* August 28, 1924) states that the use of the soft röntgen rays that have been found to be dangerous for the skin have been gradually abandoned in favor of the medium hard or hard rays. The same statement applies to the administration of massive doses, which have been abandoned in favor of fractional partial doses. Röntgenotherapy is contraindicated in all acute irritated conditions of the skin and also in cases of skin that has been previously injured by röntgen rays. This form of treatment is indicated for the purpose of epilation (recently for permanent epilation), in some forms of tuberculosis of the skin, in itching dermatoses for the relief of the itching, in eczemas, including the eczema of infants, etc. Irradiation of the thymus has not proved successful in psoriasis.

Radium in Treatment of Vascular Nevi.—F. E. Simpson (*Surgery, Gynecology and Obstetrics,* March, 1924) points out the following advantages of radium treatment for vascular nevi, accompanying this with a list of disadvantages, several illustrations, and a discussion of the technic and methods of radium treatment. Radium is unique in the fact that it exerts a marked action on the bloodvessels of the nevus, other tissues being only slightly or not at all injured. The painlessness of radium is one of its points of superiority over other methods. This factor is of importance especially in the treatment of children. If the method of application is correct, there is very little scar tissue following the use of radium. Contractures seem never to occur—a feature of great importance when angiomata are situated about the eyelids, nose, or mouth.

The cosmetic results are usually superior to those obtained by other methods. As in all cosmetic disorders, the results of treatment naturally depend very largely upon the care and fidelity to detail with which the treatment is carried out. In rapidly spreading nevi and in cases occurring in infants in which the lips are involved and suckling is seriously hindered, life may be saved by prompt radium treatment.

Acne Vulgaris.—G. Gordon Campbell (*Medical Clinics of North America,* May, 1924) considers two indications as important in the treatment of acne vulgaris; 1, to get rid of the comedones already present and to prevent the development of new ones; 2, treatment of the pus infection.

The failure of permanent cures is almost invariably due to the neglect of the first indication. The comedo extractor is the best for this purpose. Bathing with very hot water or steaming over very hot vapor helps considerably. Thorough shampooing of the skin at least once a day with a nonirritant toilet soap removes the overflow of sebum and keeps the orifices of the ducts open.

In treating the pus infection it is imperative to evacuate all pustules as soon after they are formed as possible, to prevent further infection. The whole of the comedo must be removed. The needle most satisfactory for this purpose is a straight Hagedorn. Alcohol is the most reliable antiseptic. To reduce pus formation, bacterial vaccines, either stock or autogenous, are valuable. Staphylococcus albus vaccine, in comparatively large doses, is now mostly used. For the destruction of the pus organisms in the skin röntgen and ultraviolet rays are very popular. Careful dieting and the treatment of gastric disorders are not an essential part of the treatment.

SYPHILIS

Flocculation and Complement Fixation in Syphilis.—E. W. Todd (*Lancet,* July 5, 1924) adduces evidence that the sigma reaction is more delicate than the Wassermann reaction in well treated cases of syphilis and in imperfectly treated cases of long standing, but it appears that reliance solely on either method may lead to a very small proportion of positive sera being missed. In the case of cerebrospinal fluids the sigma reaction appears to have little advantage over the Wassermann reaction, owing to the fact that in the latter reaction a much larger quantity of cerebrospinal fluid than of serum can be used, whereas in the sigma reaction the quantities are the same. From the limited number of primary cases examined it appears that the sigma reaction usually becomes positive before the Wassermann reaction, but occasionally a positive Wassermann reaction is obtained first.

Small Syphilitic Osteitic Lesions of the Cranium Detected with the X Rays.—A. Léri and P. Cottenot (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris,* April 3, 1924) report one case of epileptic seizures and three of paresis or paresthesia of the lower extremities in which clear cut x ray pictures of the skull showed small lesions of gummatous osteitis corresponding precisely in their location with the symptoms complained of. In one case there was an acquired syphilitic infection, while in two, and probably three, unrecognized congenital syphilis was responsible. In all cases the symptoms were promptly relieved by antisyphilitic treatment, and at the same time the slight palpable irregularities of the skull or unevenness of the inner table disappeared. In the epileptic case the frontal x ray picture showed a pisiform nodule to the right of the midline of the skull with subsidence of the inner table; the lateral view showed this condition of the inner table for a distance of three or four centimetres behind the bregma. Under bismuth treatment, after a single final seizure,

there was no further seizure in five months, and in two months the outline of the inner table was found to have been almost completely restored. Observation of several additional cases have convinced the authors that such conditions are relatively common.

Syphilitic Arthritis with Eosinophilia.—Alan M. Chesney, Jarold E. Kemp, and William H. Resnik (*Bulletin of the Johns Hopkins Hospital,* August, 1924) describe two cases showing the following syndrome: marked enlargement and tenderness of the lymph glands accessible to palpation; acute polyarthritis; eosinophilia; a positive blood Wassermann reaction; fever; and prompt recovery under antisyphilitic treatment. The cases are reported because of their occurrence in conjunction with a syphilitic infection.

Specificity of the Kolmer Complement-Fixation Test for Syphilis.—John A. Kolmer and Edward Steinfield (*Journal of Laboratory and Clinical Medicine,* October, 1924) found that the Kolmer complement fixation test for syphilis shows that it has three outstanding features: a very high degree of specific sensitiveness; an almost total absence of tendency for yielding apparently nonspecific reactions, and a very low percentage of anticomplementary reaction. A study of the reaction in the following conditions is made: experimental trypanosomiasis; leprosy; tuberculosis; pregnancy; diabetes mellitus; malaria; nephritis; icterus; pneumonia, and scarlet fever, with the following conclusions: Falsely negative complement fixation reactions may occur in cases of extremely latent syphilis because of insufficient amounts of "reagin" in the blood and spinal fluid. The incidence of these may be reduced by using a test yielding reactions of as maximum a degree of sensitiveness as is consistent with specificity. Falsely positive reactions are usually due to errors in technic and can be reduced to a minimum by confirming the conduct of the complement fixation test for syphilis to competent serologists unwilling to sacrifice accuracy for mere speed in returning reports or for economy of time and materials. The test did not yield falsely positive reactions with the sera of rats, guineapigs and rabbits with acute and chronic trypanosomiasis, nor does it appear to yield falsely positive reactions with the sera of nonsyphilitic lepers or with the sera of nonsyphilitic individuals suffering with the various clinical conditions listed above.

Syphilis, the Disease of Diseases.—C. Bertram Gay (*Boston Medical and Surgical Journal,* September 18, 1924) gives the following rules as those laid down for handling syphilitics in the Mayo clinic.

1. Individualize the patient. Remember that you are treating a human being not an abstraction.
2. Treat syphilis as a whole and not from the viewpoint of some isolated aspect.
3. Insist upon the combined use of mercury and arsphenamine in early syphilis, the former for spirillicidal effects, the latter for the building and maintenance of the patient's resistance. Emphasize that mercury does not control infectious lesions. Do not encourage rest intervals in the first year of an early case.
4. Taboo mercury by mouth in early cases and the use of a small number of injections of arsphenamine. If the patient cannot be given at least two courses of six injections each by the physician who has charge of him, that physician should send him to some place or agency where he can receive at least this number of injections. Use mercury by inunction and intramuscularly.
5. Emphasize the fact that inadequate early treatment for syphilis, especially the inefficient administration of arsphenamine, is responsible for grave relapses and probably for a steady increase of incidence of neurosyphilis. Insist, therefore, that early treatment shall be both intensive and prolonged. Most early syphilis is undertreated.
6. Discourage the merely symptomatic outlook on the results of treatment. In particular, the disappearance of lesions and the reversal of the blood Wassermann reaction from positive to negative in the first few years of the infection have relatively little significance. Insist that no patient shall be placed upon prolonged rest period or allowed to lapse from observation and treatment in early syphilis until the spinal fluid has been examined and found normal.
7. Emphasize the need for treatment in all patients who show evidences of syphilis, even though that evidence be nothing but a positive blood Wassermann reaction, provided the patient has never been adequately treated before.
8. In late cases of syphilis warn physicians of the danger of injudicious and overintensive treatment, and especially of the premature use of arsphenamine in patients with serious lesions of the heart, liver, and nervous system. Advise mercurial preparations.
9. Take every step possible both in early and late cases to maintain the general health and resistance of the patient and the integrity of the excretory mechanism.
10. Syphilis of the hereditary and congenital type should be treated with the same vigor and by essentially the same methods as late syphilis in adults.
11. Syphilitics should not marry within three years after infection, even when under treatment.
12. Many syphilitics have syphilitic families or contacts. Search out members of these families or the patient's other contacts and endeavor to bring them under treatment.
13. Syphilis must be treated as a whole. It is inexcusable to treat patients merely to control temporarily infectious manifestations. No agency should assume charge of a patient which is not prepared to meet every aspect of his case from start to finish and throughout the patient's life. Followup and observation are as essential as treatment.
14. Technical skill as well as trained judgment are essential to the treatment of syphilis. Emphasize how to do a thing as much as what to do.

Certain Factors in the Diagnosis of Syphilis Unrecognized in the Earlier Years of the Infection.—John H. Stokes and Harold A. DesBrisay (*Canadian Medical Association Journal,* August, 1924) say that the history of a syphilitic infection is a notoriously unreliable guide to the presence of the disease. Obscure onsets, unrecognized primary and secondary lesions, and even absence of clinical primary and secondary lesions as such, must be reckoned with in as high as twenty-five per cent. of the average diagnosed syphilis in medical consultant practice. In women the proportion is much higher. A complete medical and syphilological examination made to confirm or disprove a possibility of syphilis, has even from unpromising material, yielded sixty per cent. of positive results. This examination included the pooled resources of a group practice, plus a provocative procedure, the spinal fluid examination, detailed individual anamnesis, and study of the family.

The margin of syphilis, which, even though untreated, is Wassermann negative in the blood by ordinary technic in a diagnostic practice, is about thirty per cent. The margin of syphilis, diagnosed and undiagnosed, which is blood Wassermann negative in the average consultant practice, may reach fifty-five per cent.

Neurosyphilis is the type which, in our experience, shows a distinct tendency to Wassermann negativity in the blood, and hence calls for fuller testing by other means, especially the spinal fluid examination, to establish the diagnosis in the period of latency, when treatment may yet be of value.

Management of the Neurosyphilitic.—G. Orville Scott and Gerald H. J. Pearson (*Canadian Medical Association Journal,* August, 1924) say that the prognosis of mesodermal neurosyphilis is good both as regards relief from inflammatory symptoms and eradication of the disease. In degenerative myeloencephalitis (tabes) a few cases are hopeless, the remainder showing great clinical improvement and in a majority arrest of the disease. In degenerative encephalomyelitis (paresis) a larger percentage are hopeless but in a small majority marked amelioration is obtained and in a moderate number arrest of the process. The earlier a case of neurosyphilis is placed on proper treatment the greater the probability of cure. Without question the time to treat neurosyphilis is before clinical signs, with their indication of a possible permanently damaged neuraxis, appear. Adequate treatment of primary and early generalized syphilis is the treatment *par excellence* for neuroinfection.

No patient with symptomatic neurosyphilis should be assured of cure, but should be told that though the disease can be arrested, evidence of destructive lesions will be permanent. Neither should marriage be permitted unless the other party is acquainted with the condition, not because of the danger of transmission of the disease but because a further development may lower the patient's earning capacity. It is improbable that clinical neurosyphilis can be cured but the disease may be arrested in a large majority of cases, amounting to eradication in the mesodermal and early degenerative types and to a great improvement in the late parenchymatous varieties.

FRACTURES

Chauffeur's Fracture.—J. Grossman (*American Journal of Surgery,* November, 1924) urges that the term "chauffeur's fracture" be dispensed with, as it does not designate any specific type of fracture. He presents cases showing seven different varieties of fracture which all resulted from the same cause, namely, cranking motors.

Sectional Plaster of Paris Casing in Fractures and Fracture Dislocations.—W. A. Cochrane (*British Journal of Surgery,* October, 1924) offers the following conclusions:

1. Fractures of the bones of the leg and fracture dislocations of the ankle present difficulty, not in the actual reduction of the fracture, but in the maintenance of the corrected position while immobilization is being secured.
2. A precise, accurate, simple, and practicable method, in the form of a plaster of Paris casing applied in two or more sections, is available. The device is based upon the three piece sectional plaster method employed by Fiske in the treatment of congenital club foot.
3. The process of wedging makes fine adjustments possible, especially with reference to angular deformity.
4. In the writer's opinion and experience, the sectional plaster of Paris method should be the method of choice in all cases with displacement, where immediate reduction and fixation are indicated.

Experimental Study of Ununited Fractures with Especial Reference to the Inorganic Bone Forming Elements in the Blood Serum.—Henry A. Petersen (*Bulletin of the Johns Hopkins Hospital,* November, 1924) studied the healing of fractures in dogs on diets containing an adequate and an inadequate amount of calcium and phosphorus. The calcium and phosphorus product is much higher in the dog than in man. The calcium content is about the same, and that of phosphorus much higher.. Dogs placed on a deficient diet show chemical changes in the serum of the older animals first, though the final result of the diet is the same in all animals. The time required for the reduction of the phosphorus to a point at which fractures would not unite was from nine to twelve weeks. Once the calcium and phosphorus product has been reduced, and fractures made, nonunion invariably was the result. When the animals were placed on an adequate diet, the fractures united.

Fractures of Upper End of Humerus.—H. E. Santee (*Annals of Surgery,* July, 1924) from a number of cases deduces that fractures about the neck of the humerus occur mostly beyond middle life. The resulting disability is usually marked and prolonged. It is done mainly to the associated injury of soft tissues about the site of fracture. Wide abduction and external rotation is the position of choice for convalescence. Such position in a number of cases must be attained gradually. While recognizing the value of various types of ambulatory splints, I feel that the conditions here encountered are best and most comfortably met by bed and traction suspension treatment with a frame. Massage and physiotherapy are aids in treatment, but the best and quickest results reward the cooperative, intelligently active patient. For this reason women who resume their household duties early seem to regain function and strength more rapidly than men.

Fractures of Shaft of Femur.—W. DeWitt Andrus (*Annals of Surgery,* December, 1924) recommends a balanced traction method for treatment of fractures of the shaft of the femur in adults on the following six counts.

1. Its application can be carried out almost painlessly without anesthesia.
2. It possesses all the advantages of skeletal traction with none of the disadvantages of the latter method and can be used in certain cases, such as those associated with marked swelling of the knee joint in which the use of skeletal traction is attended with considerable risk.
3. The traction alone, if properly applied, suffices to accomplish the reduction and fixation of the fracture in the large majority of the cases; eight of the eleven in this series.
4. It permits the patient to move about in bed to a considerable extent without pain and without disturbing the force or the direction of the traction. The nursing care of such patients is therefore made much easier.
5. It can be successfully carried out in cases in which other methods fail or are not tolerated and in which open operation is contraindicated, due to the physical condition of the patient, as in two instances in this series.
6. There is less stiffness of the knee and less muscular atrophy following the use of this method than when casts alone are used.

The method is described as follows: The leg is carefully shaved and cleaned with alcohol and ether and the malleoli protected with pads. Traction straps of zinc oxide adhesive plaster are then applied to the leg below the knee and fastened to a wooden spreader provided with a cord which runs over a pulley at the foot of the bed. To this cord is attached a weight which varies according to the age and the physical condition of the patient, but is usually from twenty to twenty-four pounds in a robust individual. A sling which extends from a point just below the head of the fibula to the malleoli is then placed about the calf of the leg and provided with a rod from which a cord passes through the lower pulley of the "traveller" of the fracture frame and over another at the foot of the bed. The system is so arranged as to make the pull on the sling act at right angles to the pull on the traction straps and with one half its force.

The resultant of these two forces acts at an angle of thirty degrees with the horizontal—or directly in line with the axis of the femur with the leg in semiflexion—and is equal to the square root of the sum of the squares of the two forces. If equal amounts of weight be attached to the sling and traction straps, forty-five degrees of flexion is obtained. Thus by varying the amounts of weight we are able to vary the force of the pull and the degree of flexion to suit the requirements of a given fracture. When the upper fragment is abducted, as in many fractures of the upper third, the traction is applied with the leg in about thirty degrees of abduction.

Another sling is placed about the thigh, from which a cord runs through the uppermost pulley of the "traveller" and over the head of the bed. To it eight or ten pounds of weight is attached. This sling serves at least two purposes. In fractures of the lower third it tends to draw the upper end of the distal fragment forward into alignment with the upper fragment. In all cases it acts as a coaptation splint which supports the thigh and prevents sagging of the fragments posteriorly due to gravity. Foot drop is prevented by traction applied to the sole of the foot, the traction cord with its attached weight running over the middle pulley of the "traveller." In fractures of the lower third this may be omitted for the first two or three days to obtain a better relaxation of the gastrocnemius. Counter traction is obtained by raising the foot of the bed about eight inches from the floor.

Fractures of Shaft of Femur.—W. C. Campbell and J. S. Speed (*Surgery, Gynecology and Obstetrics,* November, 1924) submit the following conclusions:

1. Fractures of the shaft of the femur in children properly treated give excellent results.
2. Callus in children is usually exuberant, and nonunion even in the presence of infection or malposition is rare.
3. Young growing bones have the ability to correct even marked deformities.
4. Immediate reduction and plaster cast is the ideal method of reduction in children because of the uniformly good results, the ease of handling and caring for the patients and the certainty that lack of cooperation, on the part of the child, cannot displace the fragments, as often happens with the traction treatment.
5. In adults the plaster method, properly used, gives us as good, or better, results than any other method.
6. Simple fractures should be reduced immediately after injury.
7. Early mobilization of joints and massage of the soft tissues is of great importance in all fractures, but satisfactory reduction and union should not be endangered by too great an enthusiasm in this respect.
8. Compound fractures of the femur will heal without infection in fifty per cent. of the cases.
9. Nonunion is due chiefly to malposition.
10. Open reductions are rarely indicated in acute fractures of the femur.
11. Autogenous bone grafts are the best method of internal fixation in connection with open reductions; internal fixation is rarely indicated in children, even in nounions; it is indicated in malunions in adults, when reducton is difficult to maintain, and always in nonunions in adults.
12. Fractures of the femur give long periods of disability and unless properly treated are liable to result in permanent impairment.

Medicolegal Notes.

VACCINATION AS A CONDITION OF SCHOOL ATTENDANCE

The Supreme Court of Illinois holds, Burroughs v. Mortenson, 312 Ill. 163; 143 N. E. 457, that "vaccination is not a condition precedent to the right of a child to attend a public school, and cannot be made such condition either by a board of education or a board of health. The superintendent or other officers may not arbitrarily exclude from the schools a child who has not been vaccinated and refuses to be vaccinated. By rules and regulations adopted by the board, the vaccination of school children may be required in case smallpox is epidemic in the vicinity of the school or danger of an epidemic may be apprehended."

The Legislature has, by section 1, article 5, of the Cities and Villages Act, authorized cities and villages to appoint a board of health and prescribe its powers and duties, and to do all acts and make all regulations necessary or expedient for the promotion of health or the suppression of disease.

VIOLATION OF HARRISON ANTINARCOTIC LAW

The Circuit Corut of Appeals, Fourth Circuit, holds, Newman v. United States, 299 Fed. 128, that a physician cannot justify giving or selling morphine to an addict to gratify his desire for the drug, on the claim that it was given in the course of the physician's professional practice.

The Circuit Court of Appeals, Sixth Circuit, holds, Hobart v. United States, 299 Fed. 784, that the issuing of prescriptions for large doses of morphine at frequent intervals, to a known addict, who was not under restraint, was a violation of the Harrison Antinarcotic Act.

INSUFFICIENT PROOF OF MALPRACTICE IN OPERATING ON MAXILLARY BONE

In an action for malpractice, in which it was claimed that defendant was negligent in cracking or breaking the superior maxillary bone while operating for an infection of the left antrum, it appeared that, while the defendant did not discover the original source of the infection when making his diagnosis, neither could nor did the many other physicians of admitted skill and experience in that vicinity during their observations and treatments of many months. These others had the same opportunities for discovery that were possible to the defendant, and he could not be said to have shown a failure to use the reasonable care and skill which the law requires. The Wisconsin Supreme Court therefore held, De Sham v. Taugher, 198 N. W. 268, that the evidence warranted the trial court's refusal to submit to the jury the question whether the defendant was negligent in making the diagnosis.

It was also held that a finding of negligent breaking of the superior maxillary bone could have been supported only by that part of the testimony of a specialist who subsequently treated plaintiff to reduce a swelling under the right eye to the effect that if an instrument such as the defendant testified he did use had been used in a manner unusual and unnecessary for such an operation, and force had been applied to it, using a portion of the bone as a fulcrum, there could have been produced a break or crack in the superior maxillary; and that such a finding, if made, could not have stood. It would have been purely speculative, under the evidence, as to whether any such force had been so negligently applied. By this specialist's further testimony it became pure conjecture whether the bone fragments which he removed had become detached by pressure from some instrument or by pus action. In such a situation it was held that the plaintiff had not supplied the quantum of proof the law requires in order to establish liability of a defendant in this class of cases. Furthermore, it was held that it would be inconsistent with the undisputed fact that there was infection already present before defendant performed anything in the nature of an operation upon the plaintiff, and which infection, under the undisputed evidence, might have accounted for all of the unfortunate sequence. Judgment directing a verdict for the defendant was therefore affirmed.

CAUSE OF DEATH THE ACCELERATION OF DISEASE BY INJURY

In an action for death, alleged to have been the result of a collision between a buggy in which deceased had been riding and defendant's automobile, it appeared that the deceased died of Bright's disease two months after the action, that the disease had its origin prior to the accident, and that it was an adequate and probable, if not inevitable, cause of ultimate death. The only evidence of any discovered injury on deceased's person after the accident was the appearance of an abscess three days before her death. It was undisputed that this was consistent with the progress of the disease.

The Iowa Supreme Court, Pentony v. Dudley, 198 N. W. 78, held that the burden was upon the plaintiff to show, not merely the accident, but also some injury which was adequate as a probable cause of aggravation of the existing disease or acceleration of its fatality; and that the evidence failed to furnish any basis, either for expert opinion or for the finding of the jury that the alleged injury aggravated the disease or accelerated her death. Opinion or finding to that effect upon the record was held in a legal sense a mere surmise, and judgment for the plaintiff was reversed and the case remanded for a new trial.

TRANSFER OF PROPERTY OF MEDICAL COLLEGE TO UNIVERSITY

The Trustees of the Rush Medical College filed a bill requesting that it be directed to transfer its property to the University of Chicago in accordance with an agreement with the university to carry on the work of the college, the latter finding itself, because of changed conditions, unable to continue its usefulness, owing to the fact that its buildings and equipment were out of date and its facilities for instruction, according to modern standards, were inadequate, and that it had no funds with which to correct the situation. The Supreme Court of Illinois held, Trustees of Rush Medical College v. University of Chicago, 312 Ill. 100, 143 N. E. 434, that "the transfer of the property of the college to a similar charity under conditions which assure continuation of the use of the property in accordance with the purposes of the charter of the college, so that the fulfillment of the charitable purpose will be accomplished, and the efficiency of this educational institution increased, is not a diversion of the funds to a purpose foreign to that to which they were dedicated." Decree for complainant was therefore affirmed.
